FROM Prof. Giglioli's letter in NATURE, vol. xx. p. 242, it appears that the black rat is more abundant and widely distributed in Italy than in England. I know of some half-dozen specimens having been caught from time to time in the city of London, and in November, 1876, a male about six weeks old was caught, which lived in confinement for two years and three months. It was mated with a tame white one, and they had two litters of young which were black, save the feet, tip of tail, and a small brush of pure white upon the chest.

Pine Pollen and Sulphur

BY a coincidence which depends upon the season of pollen-discharge occurring at the same period in Scotland as in England, I am enabled to send you an extract from the *Haddingtonshire Courier* of June 27, which may serve to dissipate the "sulphureous theories" of Mr. Carpenter's opponents.

"The rustics in this district [Gifford] have been of late much interested in a peculiar shower which had fallen in the early morning of Monday last. All the pools on the roads were covered and fringed with a powdery substance strongly resembling the flowers of sulphur. A calculating Good Templar found that the fiery powder had been drifted more about the houses of those who loved the flowing bowl than those who loved the

contents of the flowing river. One old woman, however, dispelled the Templar's idea by stating that she had felt the smell of 'brumstane' near her dwelling, and on searching the premises it was found the water-barrel had got a saffron cap on, and was otherwise dusted with the subtle powder. As this mystery, if it is not explained, may prove serious to the nervous, superstitious, or credulous part of the community we may as well add that at this season districts in the neighbourhood of fir plantations run the risk of a thorough dusting of this powder if there is the slightest breeze, as the cones of the young Scots fir are thickly coated with yellow powder or pollen, which will give out a blinding saffron cloud on the slightest irritation."

The laudable desire of our newspaper correspondent to relieve the anxieties of his neighbours at a time when the Presbyterian world is much exercised over the question of eternal and sulphureous punishment, can be fully appreciated only by natives. But in my opinion, the correspondent, in his clear knowledge of the nature of the "brimstone" deposit, exhibits a most praiseworthy tendency to explain the natural in terms of the natural; whilst the incident tends to show at the same time that there are not a few persons in this world to whom a course of elementary studies in natural history would serve as a means of culture, not to say of common protection against ludicrous mistakes such as those against which Mr. Carpenter inveighs. Plague of Rats

I SEE by NATURE, vol. xx. p. 65, that Mr. Orville A. Derby contributes some very interesting information relating to a plague of rats in Brazil, and adding that the plague "is said to occur at intervals of about thirty years, and to be simultaneous with the drying of the *Taquara*, or bamboo, which everywhere abounds in the Brazilian forests." It may be interesting to know that a similar plague of rats visited the higher coffee districts of Ceylon during the year 1875, doing great damage to young and old plantations alike.

It is remarkable that the invasion of rats was simultaneous with the flowering and death of the *Nilloo* (*Strobilanthes*), which forms the greater part of the underwood of Ceylon forests, and is said to flower and die once every seven years. The most remarkable part of the plague was that the rats did not seem to devour any part of the branches they cut off, but to nip off and leave them untouched upon the ground. So serious indeed was the damage done, that on some coffee estates rewards were given to coolies for every rat they caught, and it was not an uncommon thing to hear of three or four hundred rats being destroyed, on *one* estate only, per week.

Between the years 1840 and 1850 there was a similar plague in the Kalebokka coffee district, where the damage done was immense, but I am not aware if it was so general as in the rat plague of 1875. It is to be hoped that we may not again be invaded in 1882, when the *Nilloo* is next expected to die.

Ballangoda, Ceylon, June 16 FREDERICK LEWIS

Glow-worms

SHELLEY sings of a "glow-worm golden in a dell of dew," but last night, at 10 o'clock, while travelling on a bridle path among the bleak lonely mountains of Tynron, Dumfriesshire, bearing up against a high wind with cold rain, I espied three glow-worms shining among the grass and ferns. I had seen them in the same locality before, but scarcely expected to have noticed them in such ungenial weather when summer has with us scarcely yet begun. J. S.

July 8

Headless Butterfly laying Eggs

ABOUT three o'clock on the 11th inst. I picked up a butterfly, probably belonging to the genus *Vanessa*. It was a female, the head of which had recently been plucked off by a bird, and was lying near the body. Thinking it was dead, I carried it home to examine the wing scales. On clipping off a bit of wing about four hours afterwards, the legs moved, and in a short time an egg was laid. In about two minutes another egg was laid. Others followed, till five-and-twenty had been expelled. Tremors of the legs and wings accompanied each deposit. The laying ceased, and the headless mother seemed dead. Next morning, on touching her, the motions of the legs and wings were repeated, and in a short time the laying was resumed. On close examination a heaving of the wings and rings of the abdomen could be observed, with about the frequency of human breathing. At the end of twenty-nine and a half hours from the time of finding, the laying ceased; seventy-eight eggs were laid by the butterfly with her head off. A. STEPHEN WILSON

THE COMPARATIVE ANATOMY OF MAN[1]

III.

The Mongoloid People of Asia

TO the north and east of the line already spoken of, running northwards from the head of the Bay of Bengal to the north of the Caspian Sea, the bulk of the people of the Continent of Asia belong to the Mongolian, or better, Mongoloid type.

The physical characters of these people, best seen in the so-called Tartars who inhabit the country to the north of the great wall of China, are as follows: the complexion is pale brown, usually with a yellowish tinge; hence they are spoken of as the "yellow races," in contradistinction to the (so-called) white and black races. Their hair is black, perfectly straight, and coarse. In microscopic section it is seen to be of large size, and more inclining to cylindrical than in other races, but it varies much. Except on the scalp, where the hair is often long, the capillary development is very scanty. On the face it is often limited to two slender pencils on the upper lip; and the beard, when developed, is acquired comparatively late in life. The face is broad and flat; the space between the eyes is wide; the nose small, straight, and compressed; the eyes dark and small; the aperture between the lids narrow and somewhat oblique, being raised at the outer corner; the upper lid drooping, the inner corner partly covered by a vertical crescentic fold of skin; the cheeks very prominent; the mouth and lips of moderate size, the lower lip often hanging; the chin small and sharp.

The osteological characters of the typical Mongolian are more marked in the face than in the cranium, for the latter may vary between the extremes of brachycephaly and dolichocephaly, though the former prevails. The face is large, being both high and broad; the forehead flat, the glabella and superorbital ridges slightly developed; the orbits round, with thin sharp margins, the sub-glabellar nasal depression very slight; the nasal bones narrow and flat; the whole framework of the nose inclining to the leptorhine form; the jaws of medium prominence; the arch of the mouth broad and round; the malar bones both broad and deep. Perhaps the most distinctive feature of the Mongoloid face, which gives it the characteristic appearance, is the forward position of the outer margin of the orbit, as compared with the median line of the face. In order to estimate this character with exactness, Prof. Flower measures the angle formed between two horizontal lines meeting at the most depressed point of the nasal bones in the middle line (the apex of the angle) and resting on the middle of the outer margins of the orbit. This *nasi-malar* angle gives valuable average results. For instance, the average of 130 European skulls is 131 deg., of the twenty Maravars mentioned in the last abstract, exactly the same; of 20 African negroes 134 deg., and of 20 Australians 135 deg. In all of the true Mongolian races, the average exceeds 140 deg. Thus, in 4 Samoyedes it is 144 deg.; in 16 Chinese, 142 deg.; in 7 Japanese, 141 deg.; in 4 Burmese, 144 deg.; in 26 Eskimo, 144 deg.

The Mongoloid races of Asia are conveniently divided into two groups, the northern and the southern. The former, called Mongolo-Altaic races, are united by languages having considerable affinities. They nearly all lead a nomadic life, depending for their living on hunting, fish-

[1] Abstract of Prof. Flower's Hunterian Lectures, delivered at the Royal College of Surgeons, commencing on Wednesday, March 5. Continued from p. 246.

ing, and cattle-breeding. Occasionally, when united under the leadership of some military chieftains of extraordinary capacity, as Attila, Tchinghis Khan, and Timur, they have overrun nearly the whole of the continents of Asia and Europe; now, however, they are everywhere either the actual subjects, or live by sufferance, of the people over whom they formerly terrorised—the Russians, Chinese, &c.

The anatomy of these races is only represented in the museum by a complete skeleton and several skulls of Samoyedes, a people now inhabiting the most inclement parts of North-western Siberia. They were conquered by the Russians in 1499. They are dwellers in tents made of pieces of bark covered with reindeer skins, and live chiefly by fishing and the chase, and by the produce of the herds of reindeer which they keep. Their external physical characters are always described as being typically Mongolian. Their skulls are very broad and low, the average latitudinal index of four being 847, and the average altitudinal index 719. They are, therefore, decidedly brachycephalic. The orbits are round (megaseme), the average index being 938; the nasal index is 431, so that they are truly leptorhine; the alveolar index of 102 shows them to be mesognathous, with a strong inclination to prognathism. The skeleton, that of an old male, is slightly below five feet in height. The pelvic index is only 78, but both bones of the upper extremity are disproportionately long compared with those of the lower limb, and the radius and the tibia are relatively longer compared with the proximal segments of the limbs than in Europeans.

The Turks, the Magyars, the Finns, and other representatives of the Mongolian type, have for so many generations intermingled with the people through whom they have passed in their migrations, that their original physical characters have been completely modified. Even the Lapps, a diminutive race of nomads, inhabiting the most northern parts of Europe, supposed to be of Mongolian descent, show so little of the special attributes of that race, that it is difficult to assign them a place in a classification based on physical characters. Their crania are remarkably capacious, one in the collection being as large as 1,800 c.c., and another 1,600. They are brachycephalic, have a latitudinal index (average of seven) of 812. The orbital index of the same number is 984. The nasi-malar index, though lower than in the true Mongolian, being about 136°, is higher than in the other Europeans.

Races of Eastern Asia

Many races of Asia, of similar physical type to the Mongolian, are divided from the Altaic group by language and by mode of life. One large group is formed by the people of Thibet and Burmah, with various tribes dwelling within the north-eastern frontiers of India. The four Burmese crania in the museum are all short, high, round, or rather square skulls; the average latitudinal index is 82, and the altitudinal index nearly as high. The orbital, nasal, and alveolar indices are all moderate. The nasi-malar angle of 144° is thoroughly Mongoloid. From the Burmese, the transition (physically) to the Malays is very easy; and through the Malays, the purer races of the Polynesians are connected with the inhabitants of Central Asia.

The various races constituting the population of the vast empire of China all belong to the Mongolian type, and have gradually moved southwards to their present dwelling-places. The existing reigning dynasty is Mandschurian, belonging to the Tungus branch of the Altaics. The Chinese proper formed their earliest settlements in the north-western provinces of what is now called China about 2000 B.C. The aboriginal tribes they found there still exist, as the Miaw or Miautze, &c.

The following cranial characters of the Chinese are deduced from sixteen specimens of the male sex:—The average capacity is 1,424. The index of breadth is 782, so they fall under the mesocephalic category, inclining to brachycephaly. All the other Mongolian races hitherto treated of have been decidedly brachycephalic. The height-index is lower, viz., 753. The general form of the face is Mongolian, the forehead smooth, with little development of the glabella, the space between the orbits wide, the malar bones large and prominent, the anterior root of the jugal arch stands out laterally from the face, then turns sharply backwards beyond the maxillo-jugal suture, instead of gradually sloping backwards from that point, as in the English skull. The nasi-malar angle is 142 deg. The orbital, nasal, and alveolar indices are all medium, being respectively 869, 504, and 993.

The Japanese differ entirely from the Chinese, and resemble the Altaic races in the polysyllabic character of their language. They appear to have migrated from the Asiatic continent to the islands they now inhabit in the seventh century B.C., first taking possession of the southernmost island, Kiu-siu, and soon afterwards passing on to Niphon, gradually driving out the original population, the Ainos. It is, however, probable, that some portion of the latter became absorbed into the conquering race, which circumstance may account for part of the diversity of features and type seen among them. In the main the physical characters of the Japanese are Mongolian. At present we have really very little information about their anatomy. There are but six male skulls in the College Museum, which give the following averages:—Capacity, 1,486; latitudinal index, 771; altitudinal index, 753; orbital index, 910; nasal, 472; alveolar, 971; nasi-malar angle, 141 deg.

The people who inhabited Japan before the Japanese are called the Ainos. They have lately attracted much attention from ethnologists, owing to the fact that in their physical characters, manners, and customs, they entirely differ from all the other races of the part of the world in in which they dwell. They formerly inhabited the whole of the Japanese islands, Saghalien, and the Kuriles. They are mentioned in Chinese books before the time of Confucius, under the significant title of the villous or hairy men, and are called by the Japanese, "Mo-sins," a word having the same signification. "Aino," in their own language, means "the men," or "the people." Their numbers are now extremely reduced, and the territory they occupy limited by the encroachments of the Japanese from the south, who have driven them up to the most northern part of the island of Jesso, while the Mandschu Tartars have taken from them more than two-thirds of the Island of Saghalien. Though their language has received a considerable infusion of Japanese and Mandschu words, it appears to be of fundamentally different origin. They have no agriculture, and live principally by fishing and hunting, shooting deer and bears with the bow and arrow. They appear to be good-natured, honest, and of a mild, contented disposition.

In stature they are short (the men about 5 feet 2 inches in height), but stouter made, and more hardy and muscular, than the Japanese. Their head is large, their colour rather dark; their forehead low, the superciliary ridges prominent, the nose straight, short, and thick, and rounded at the end. The eyes are open, and not oblique like those of the Mongols, and bright, sparkling, and intensely black. What distinguishes them most in external appearance from all the surrounding races is the abundant development of their hair and beard, but this has been much exaggerated; it is black, coarse, straight, and shaggy; that on the head is worn long over the shoulders, and mingles with the beard. The few skulls known are heavy, and have the muscular impressions strongly marked. The average altitudinal index of four in Dr. Barnard Davis's collection is 78; of three measured by Prof. Flower, 74·3. These present none of the

features characteristic of Mongolian skulls, the facial bones being more European in type, and the nasi-malar angle only 129 deg. The affinities of the Ainos are at present a matter for speculation.

The Eskimo

The original inhabitants of the whole of the New World are light brown, or copper-coloured, have straight black hair, and show, amid considerable diversity in detail in particular regions, a far greater resemblance than can be found in any other portion of the world's surface of equal extent. The Eskimo, inhabiting the most northern portion of the continent, stand, in many respects, apart from the others, and are evidently quite as nearly allied to some of the Asiatic races as they are to the Americans. These people call themselves *Innuit*, which signifies nothing more than "the men," or "the people." The word *Esquimaux*, as it is rendered in French, or *Eskimo*, in the Danish method of spelling, now usually adopted in this country, was applied to them by a neighbouring tribe of Indians, and is said to mean "eaters of raw flesh." They dwell in various scattered localities near the northern coast of North America and the great adjacent islands, from Behring's Straits to Greenland, and on the north coast of Labrador. Like the Mongolo-Altaic races of Asia, they lead a nomadic life, modified somewhat by the peculiarities of the surrounding physical conditions, dwelling in tents in summer, and in houses of snow in winter. Agriculture being impossible in such a climate, their only means of subsistence is hunting and fishing. The flesh of seals, cetaceans, and reindeer forms their principal food. In the pursuit of the two former by sea they use boats, which they manage with great dexterity. They train dogs to draw their sledges, but, unlike the Laplanders, do not domesticate the reindeer. They clothe themselves comfortably in dresses of skin, and employ bows, arrows, and harpoons in the chase. In Greenland they have reached a considerable degree of civilisation, but even here, as elsewhere, their numbers seem to be diminishing.

The Eskimo are generally below the middle size; their head is large, their legs short, and their hands and feet small; their complexion is dusky or swarthy. Their hair is black, straight, and coarse, the beard and moustache generally scanty, though sometimes moderately developed. The eyes are small, black, and sparkling; the elevation of the outer end of the aperture and the vertical fold covering the inner canthus, spoken of before as characteristic of the most typical Mongolian races, have often been observed in them. The nose is usually straight and narrow, and more or less sunken between the prominent cheeks. The mouth is large and the lips rather prominent, generally kept somewhat apart. The chin is small and pointed.

The College Museum contains as many as twenty-seven adult skulls of Eskimos, twenty-four of which are in a condition to form reliable measurements. Of these seventeen appear to be those of males and seven of females.

A typical Eskimo skull always presents such marked characters that it can never be mistaken for that of any other of the groups of mankind. It is of very large size, especially in relation to the rather small stature of the people, the average capacity of 17 male crania in the collection being 1,546 c.c. or 94·3 c. inches. This is almost exactly the same as the average English (of the lowest class), but it exceeds that of 74 modern Italian males by 71 c.c., and it is above the average of Australian males by as much as 261 c.c. or 16 c. inches. The large size of the brain of all hyperborean races, Lapps as well as Eskimo, seems not necessarily to be connected with intellectual development, but may have some other explanation not at present quite apparent. The next distinctive character of the Eskimo skull is its great length and narrowness, especially in the upper part. The base is fairly broad, and the mastoid processes are well developed; but, instead of expanding upwards to the parietal region, it narrows, and, towards the median line above, contracts so rapidly that the upper part of the skull has the form of the roof of a house. Measurements of various series of Eskimo skulls give remarkably uniform results as regards the latitudinal index, the average being from 71·2 to 71·4, so that it may be considered as perfectly established, that the Eskimo are among the most dolichocephalic of races. The female skulls are somewhat broader than the male. The index of height is somewhat greater than that of breadth, averaging 73·5. The cranial sutures are very simple; and among the specimens examined there is no case of metopism or persistence of the frontal suture, nor is there any case of the squamosal bone meeting the frontal at the pterion.

The whole face is large, both high and broad; the forehead is flat, the glabella little developed; the orbits are round, and the malar bones of great size and very prominent, giving a nasi-malar angle of 144 deg. The nasal bones are small and narrow, often coming to a point at their upper ends, and the whole aperture is very long and narrow. The Eskimo are, in fact, the most leptorhine of all races; the average nasal index of the 17 male skulls before spoken of, being only 42·2, the average of European crania being about 47, and that of Australians 56. The projection of the jaw is moderate, giving an alveolar index of 100·8, which brings them into the mesognathous category, with an inclination towards prognathism. The arch formed by the series of teeth is remarkably short, broad, and round. The teeth are small, and generally become worn down to stumps as life advances.

Two out of the three Eskimo skeletons in the Museum possess one more than the usual number of vertebræ, the additional one being interposed between the dorsal and lumbar series, and partaking of the character of both. The brim of the pelvis is remarkably wide transversely, and thus, as also in the limbs, they deviate widely from the negro type: for example, the humero-radial index, which in the Andamanese is as high as 82, in Negroes 79, in Australians 77, and in Europeans 74, does not exceed 71·3 in either of the three skeletons, the average being 71·1.

Dr. Barnard Davis has shown that the special peculiarities of the Eskimo skull are most marked in Greenland; there is also good evidence that the Eskimo have migrated from the west towards the east, and did not reach Greenland, at all events in its southern parts, until the fourteenth century. Their affinities, moreover, as shown by physical characters, are more with the inhabitants of North-Eastern Asia than with the American Indians, and it is not at all improbable that they are derived from the same stock as the Japanese. In this case the peculiarities by which the Eskimo are differentiated from the Asiatic Mongolians cannot have been developed by crossing with other nations, on account of their complete isolation, but must be attributed to those gradual modifications, produced by causes at present little understood, by which most of the striking variations we have met with in the human species have been brought about; modifications more strongly expressed the more completely isolated the race has become, and the further removed from its original centre of distribution.

OUR ASTRONOMICAL COLUMN

THE DUNSINK OBSERVATORY, DUBLIN.—The third part of "Astronomical Observations and Researches made at Dunsink, the Observatory of Trinity College, Dublin," has been published by Dr. Ball. It contains four papers, the first by the previous director, Dr. Brunnow, presenting a discussion of observations of the

planetary nebula H. IV. 37, the position of which is in R.A. 17h. 58m. 36s., N.P.D. 23° 21′·8 for 1880. The nebula appears in the South-refractor as a somewhat elliptical disk, whose major axis is about half a minute, and has in the centre a well-defined point resembling a star of the eleventh magnitude. This point was compared in declination with a star to the north of the tenth magnitude, preceding the nebula by 25s., the same method of observing being used that had been adopted in Dr. Brunnow's earlier researches on stellar parallax. The observations extend over thirty-three nights, from 1871, August 13, to 1872, August 6, and their discussion gives for the parallax of the nebula, + 0″·047 ± 0″·030. Prof. Bredichin, in "Annales de l'Observatoire de Moscou," vol. iii., has found a negative parallax (− 0″·064 ± 0″·039), using also the method of differences of declination with the same star of comparison. The results of these investigations may be taken to indicate that the parallax of this planetary nebula if measurable at all must be very small. The second paper contains Dr. Ball's observations of 61 Cygni, and his determination of its parallax therefrom. By what was at first an inadvertence, instead of using the following of the two components as Dr. Brunnow had done, the preceding one was observed, and the mistake not being remarked until the series was considerably advanced, it was resolved to complete it as begun; perhaps the result possesses for this reason additional interest. Dr. Ball finds for the parallax + 0″·4654 ± 0″·0497, which is about a mean of the values obtained by Bessel, Johnson, Peters, Struve, and Auwers, which appear entitled to the greatest weight. The observations extending from 1877, July 3, to 1878, June 1, are given in their original form. The third paper, also by Dr. Ball, relates to "observations in search of stars with a large annual parallax," forty-two stars being examined for this purpose, including several red and variable stars: the results, however, are found to be entirely negative as regards the object in view, no amount of parallax worth following up being suggested. The principle upon which the observations were made is fully described and their details appended to the memoir. The last portion of the Dunsink publication contains Dr. Brunnow's measures of double-stars 1870–73.

THE SOLAR ECLIPSE OF JULY 19.—The Observatory of Paris is situate very close upon the northern line of simple contact in this eclipse, which will add interest to observations that may be made there. The *Connaissance des Temps* employing the lunar tables of Hansen and the solar tables of Leverrier, gives the magnitude of the eclipse only 0·013 (the sun's diameter being taken as unity), commencement at 7h. 46·1m. A.M. mean time at Paris, ending at 8h. 5·4m. At Gibraltar the magnitude of the eclipse will be 0·32 at 7h. 9m. local mean time, and at Malta 0·38 at 8h. 46m. As we have before remarked the only civilised station where a great eclipse is likely to be witnessed is Aden. The eclipse is strictly an annular one, but the moon's augmented semi-diameter is only five seconds less than the sun's semi-diameter, where the greatest phase occurs near apparent noon. At Aden at 0h. 12m. P.M. 97-100ths of the sun's diameter will be covered by the moon; the line of annular eclipse falls upon the opposite African coast.

PERIODICAL COMETS IN 1880.—Two known comets of short period will be observable before the end of the ensuing year, viz., Winnecke's, which may be in perihelion early in December, and Faye's, which, according to Dr. Axel-Möller, again arrives at its least distance from the sun in January, 1881. The perturbations of Winnecke's comet during the actual revolution will not be important, and from Prof. Oppolzer's elements of 1875 it seems likely that difficulty may be experienced in securing observations, the track in the heavens if we assume the time of perihelion passage to be December 1·5 being as follows:—

1880–1.	Right Ascension. ° ′	Declination. ° ′	Dist. from earth.
Oct. 2	196 29	− 0 15	2·223
Nov. 1	224 3	− 11 35	1·944

METEOROLOGICAL NOTES

THE Eleventh Contribution to Meteorology by Prof. Loomis appears in the *American Journal of Science and Arts* for this month. With the view of inquiring whether areas of low atmospheric pressure sometimes result from a circulation of the surface winds not extending to a height of 6,000 feet, Prof. Loomis has examined eighty-nine storms and compared in each case the average direction and force of the surface winds near the base of Mount Washington with the winds at the top of the mountain. In the majority of those cases in which a storm with its area of low barometer passes over the New England States, the usual system of circulating winds which prevails at the surface, does not extend to the height of 6,000 feet. In cases, however, when the depression is unusually great, this system of circulating winds extends to that height. When the system of circulating winds reaches to the top of Mount Washington, the change of wind into the east usually begins near the base eleven hours sooner than on the top of the mountain; and the change subsequently into the west usually begins at the base five hours sooner than on the top.

IN the same paper Prof. Loomis examines eight storms, the average courses of which were approximately from south to north, and six storms which travelled from north to south, with the view of obtaining information from such abnormal storm paths, regarding the causes which determine the movement of storms with their low barometers from place to place. These two groups of storms present characteristics very different from each other. As contrasted with the other group, storms moving to northward show a central pressure, becoming more depressed as they advance; the southerly winds accompanying them are marked by a greater humidity and velocity; and the rainfall is very greatly in excess. If attention be exclusively directed to storms moving to northward the facts seem to favour the idea that in a great storm the condensation of vapour is an efficient cause which controls the movement of the winds. Storms moving to southward, however, show very different results, areas of low pressure being observed to be formed with little rain and sometimes even with none at all. The general conclusion the inquiry seems to point to is that the initial depression of the barometer is the result of a system of circulating winds, the most frequent cause of which is two or more areas of high pressure at considerable distances, often 1,400 miles from each other, differences of temperature and humidity being important agents in producing, but more especially in maintaining, such a system of winds. If this be so, then the points in the inquiry calling for the most serious attention are the causes which conspire in bringing about those wide areas of high pressure round a region of lower though still high pressure and the concentration of moister and warmer air over this region.

THE *Results of the Meteorological and Magnetic Observations for* 1878 made at Stonyhurst College have just appeared. To the routine work of the observatory has been added the preparation of an agricultural report sent weekly to the Meteorological Office; and to the usual observations are added observations of crops, flowers, shrubs, and trees, and a complete and very valuable table

of the directions in which the upper clouds (cirri) were observed to move during the year with the dates, and the direction and force of the surface winds at the same times. The meteorological observations made at Kerguelen Island during the Transit of Venus Expedition have been discussed, together with those made on board the *Challenger* and the *Erebus* and *Terror;* and the three series of results have been handed over to the Meteorological Office for publication. Their appearance will be looked forward to with the greatest interest on account of the well-marked and extraordinary differences between the daily fluctuations at Kerguelen Island and those in similar latitudes of the northern hemisphere. An extremely interesting table is given showing the monthly rainfall for the thirty years ending 1877. The results show a maximum in October and a minimum in April and May, which agree with the same phases of the rainfall over similarly situated places in this part of Great Britain. The curves of amount and frequency of rainfall show an increase during the past twenty years. They show also a minimum about 1855, and, though not a minimum, yet a distinctly marked depression about 1866, the next minimum sun-spot.

FROM the "Results of the Rain Observations made in New South Wales during 1878," just published under the superintendence of Mr. Russell, Government Astronomer, we learn with extreme satisfaction that this important element of climate is now being observed at ninety-six stations, fairly well distributed over the Colony. A large map accompanies the report, showing the positions of the rain-stations by black circles, the size of which are proportional to the amount of the rainfall for the year, the largest being Fort Macquarie, on the coast, representing 62·50 inches, and the smallest Lake Boulka, 5·61 inches. Setting aside a few local deviations, due to physical configuration, and probably in one or two cases to the shortness of the period (one year), the amounts show, as was to have been looked for, a gradual diminution from the coast inland. The manner and amount of this diminution over the different districts the observations of future years will disclose. The results of this system of observation, taken in connection with the systems of Queensland, South Australia, West Australia, and Victoria, will in a few years go far to solve the important practical problem of the distribution of the rainfall over Australia. An interesting table is given of the mean height above summer level of the Murray River at Echuca, thirty miles south of Deniliquin, from 1863 to 1878. The annual amounts show decided minima about 1866 and 1877, separated by a maximum about 1871; and the monthly amounts a great excess from July to December, when the mean height above summer level is 17½ feet, as compared with 5⅓ feet of mean height during the other six months. The annual maximum floods varied from 18⅓ feet in 1855 and 1877 to 38 feet in 1870, and the average date of their occurrence is early in October.

GEOGRAPHICAL NOTES

IN its issue for July the *Financial and Mercantile Gazette* of Lisbon publishes a map of a portion of Africa, for which it is indebted to the courtesy of Major Serpa Pinto, and on which that explorer's course through the Dark Continent is laid down. The map is rendered the more interesting by the fact that it also shows the routes followed by Livingstone, Cameron, and Stanley. Last night, as we intimated last week, Lord Northbrook, as President of the Geographical Society, gave a reception in Major Pinto's honour, at which a large number of eminent geographers and others were present.

THE Tlemcen *Courrier* (Algeria) describes a large subterranean lake recently discovered at the Cascades of Tlemcen. The opening seems to have been brought to light by some workmen who blasted a large rock at the Cascades. Entering in a rude boat the cave thus exposed they sailed for about three kilometres by the aid of torches, which revealed magnificent stalagmitic columns joining the roof and the bed of the lake. The other end of the lake seems to give off a stream at Sebdou supposed to form the source of the Tafna. The account given by the *Courrier* is rather vague. It states the lake abounds with blind fish, many of which were caught.

THE first number has reached us of a new monthly periodical, entitled *L'Afrique explorée et civilisée* (Geneva: Sandoz), to the prospectus of which we referred recently. It does not contain much new information, except, perhaps, as regards the Belgian Congo flotilla, the proceedings of which we shall watch with great interest. With the endless misfortunes of the International Association's land expedition in Eastern Africa before our eyes, we fear that great things must not be expected, unless, indeed, Mr. Stanley be eventually placed in supreme command. The number contains a map of the continent, which has been specially prepared by Lieut.-Col. Adan, the head of the military cartographical establishment at Brussels, and on which are shown the routes of recent explorers of Africa.

THE *Colonies and India* furnishes some interesting information in regard to the geographical aspects of the scheme for constructing a railway across the Sahara from Algeria to Timbuktu. An expedition is to start in September to make a careful survey of the route, and in order that it may be supplied beforehand with the best information procurable, prizes to the value of 200*l*. are offered for the best papers descriptive of the country between Golaeh and Timbuktu. Opinions appear to be conflicting as to the practicability of the scheme. M. Soleillet, whose recent journey in West Africa we have before alluded to, thinks unfavourably of it; but MM. Foureau and Fau, who have lately explored a large part of the country south of Algeria, aver that the so-called desert is hardly a desert at all.

UNDER the title of "Le Laos et les Populations sauvages de l'Indo-Chine," the *Tour du Monde* has just commenced the publication of an account by Dr. Harmand of his travels in the interior of the Indo-Chinese peninsula in 1877. The narrative is illustrated by well-executed and interesting engravings from sketches and other material furnished by the author.

THE leading paper in the June number of the *Bulletin* of the Paris Geographical Society is an Introduction to the Monuments of Geography by the late M. Jomard, edited by M. E. Cortambert; the present instalment is mainly a history of the progress in the art of map construction. M. Opegez describes a journey made by himself and some companions from Buenos Ayres to Jackal at the foot of the Andes, and Prof. Paul Chaix contributes interesting notes on Siam, an Egyptian Calendar, and the First Meridian; he does not see any inconvenience in the present variety of first meridians. We are glad to see that the *Bulletin* is getting more and more prompt in publication.

IN No. 81 of the *Zeitschrift* of the Berlin Geographical Society Herr K. Himly treats at considerable length of two Chinese cartographical works, and Herr Beuster, a German missionary, gives the result of his observations on the Vainenda, an African people settled in the north-east of the Transvaal "Republic," as he still calls this British possession. The *Verhandlungen* of the same Society, No. 6, contains a paper by Dr. Junker on his three years' travels in Central Africa; while Dr. Kiepert briefly describes some recent explorations to the north-east of the Caspian Sea, hitherto but imperfectly known.

PROF. MOEBIUS ON THE EOZÖON QUESTION

THE eminent zoologist, Dr. Karl Moebius, of Kiel, has recently published a treatise, "Der Bau des *Eozöon canadense* nach eigenen Untersuchungen verglichen mit der Bau der Foraminiferen" ("The Structure of *Eozöon canadense*, according to my own Investigations, compared with the Structure of Foraminifera"), which first appeared in the "Palæontographica" (vol. xxv.), and was afterwards republished separately. Prof. Moebius inclines entirely towards the view of King and Rowney

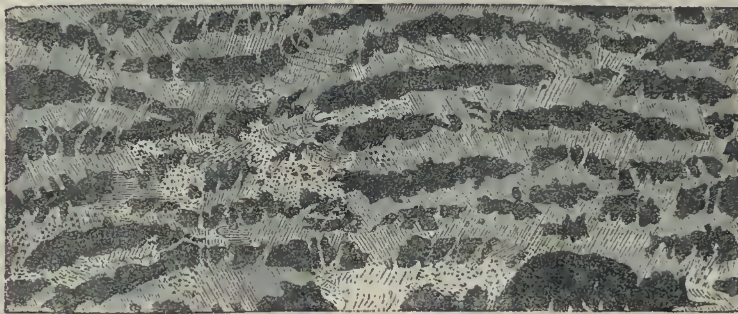

FIG. 1.

(*Proc. Roy. Irish Acad.*, ser. 1, x. and ser. 2, i.) disputing the organic character of Eozöon. The question is one of such great interest, and the paper is so sure to originate controversy, that we have no doubt the following abstract of the chief points in Dr. Moebius's treatise will be welcomed by our readers.

After a concise account of the history of the Eozöon question, since the remarkable discovery by Prof. Dawson and the detailed investigations made by Prof. Carpenter, Dr. Moebius commences the discussion of the subject by stating that he was first led to the study of Eozöon through observation of the structure of a

FIG. 2.

rhizopod, found by him in 1874 on the coral reefs near Mauritius, and to which he had given the name of *Carpenteria rhaphidodendron*. This consists of tree-shaped individuals which often form turf-like growths of several centimetres in length, breadth, and height. Sections of such growths surprised Dr. Moebius by their great likeness to the representations of Eozöon sections accompanying the descriptions published by Dawson, Gümbel, Fritsch, &c. He therefore resolved to make a careful investigation of Eozöon and to compare it with *Carpenteria rhaphidodendron* and other foraminifera, in order to form his own judgment regarding its nature, and to

establish such reasons and facts as might lead to a generally acceptable and final decision of the Eozöon question.

Fig. 3.

With this object in view Dr. Moebius investigated upwards of ninety Eozöon sections, of which many were placed at his disposal through the kindness of Dr. Carpenter, and of which many others originally belonged to Prof. Dawson; there was no doubt, therefore, that the sections possessed those properties which had led the latter to declare the formation to be of animal origin. According to Dr. Moebius *Eozöon canadense* consists principally of alternate layers of yellowish green serpentine and whitish limestone. Fig. 1 is the representation of a good Eozöon section, magnified four times.

The darker parts represent the serpentine, the lighter ones the limestone which in many places completely surrounds little rounded nodules of serpentine. Both the limestone layers, as well as the serpentine layers, have indentures and frequently end in wedge-shaped points. They generally attain a thickness of two or three millimetres. In the limestone, even when magnified only four times, the straight and parallel division lines of the thin layers of which it is composed are easily seen. Besides these division lines groups of little dots or of curved lines are noticed, representing stems and thin plates imbedded in it. These stem- and plate-shaped formations, which are of great importance with regard to the introduction of Eozöon amongst foraminifera, will be better recognised in Fig. 2.

This represents a small part of an Eozöon section, from which the limestone has been dissolved by hydrochloric acid, magnified forty times, under reflected light. The acid has only left the serpentine and the stems and plates, which, like serpentine, consist principally of silica

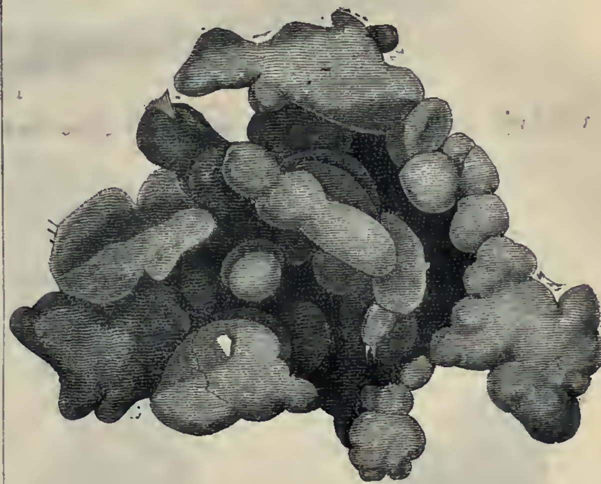

Fig. 4.

and magnesia. Between the indented bands of serpentine (s s) we see cavities which were formerly filled up by carbonate of lime. From the bottom of these cavities, which also consists of serpentine, stems and plates of

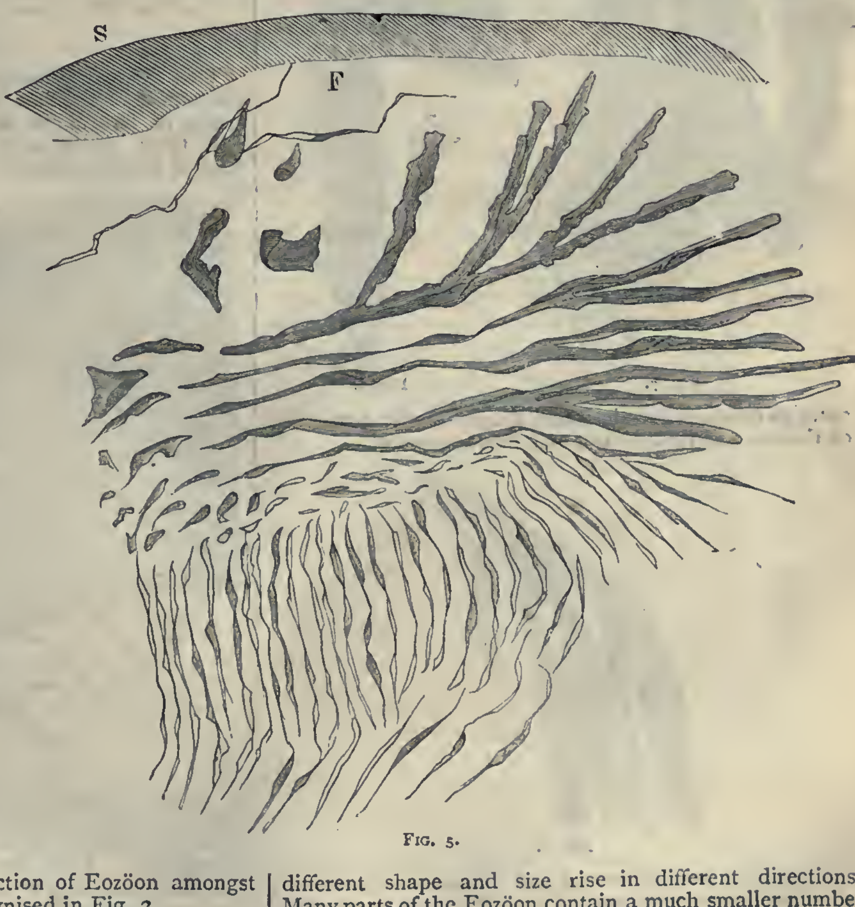

Fig. 5.

different shape and size rise in different directions. Many parts of the Eozöon contain a much smaller number

of stems than are shown in Fig. 2, such as the piece represented in Fig. 3, where the lime is also removed, and which is also magnified forty times. Still poorer in stems is Fig. 4, where only a few nodules of serpentine are pro-

FIG. 6.

vided with stems. Figs. 3 and 4 may at the same time serve to illustrate certain round shapes in the serpentine of Eozöon and their almost spiral arrangement.

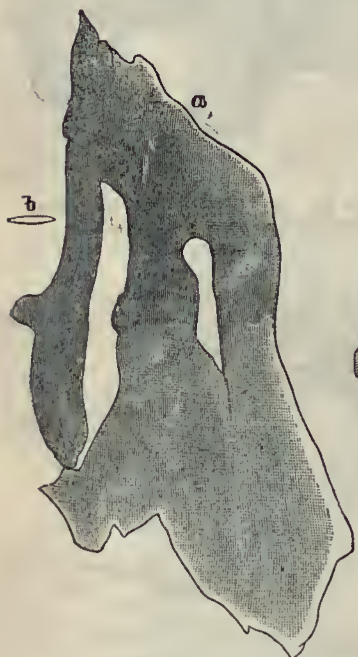

FIG. 7.

FIG. 8.

FIG. 9.

If Eozöon sections are cut and ground to such thinness that they become translucent, then they may be examined by yet more powerful microscopes and under transmitted instead of reflected light. Most of the stems then appear distinctly as simple or ramified, bent plates, giving generally concavo-convex, much less frequently bi-convex or oval cross-sections, as illustrated by Fig. 5.

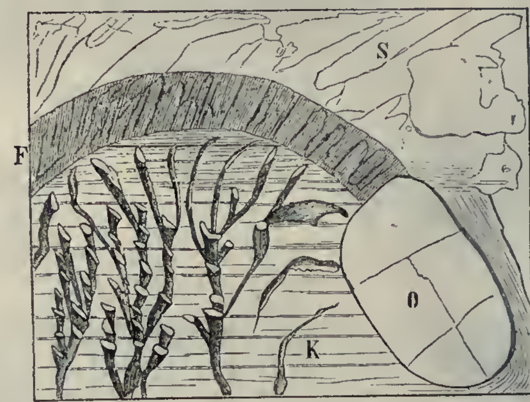

FIG. 10.

This figure represents stems magnified 150 times. A the margin of the lime in which the stems are imbedded bands of fine fibres are seen; we shall refer to these and their significance with regard to the introduction of Eozöon amongst foraminifera. Perfect certainty

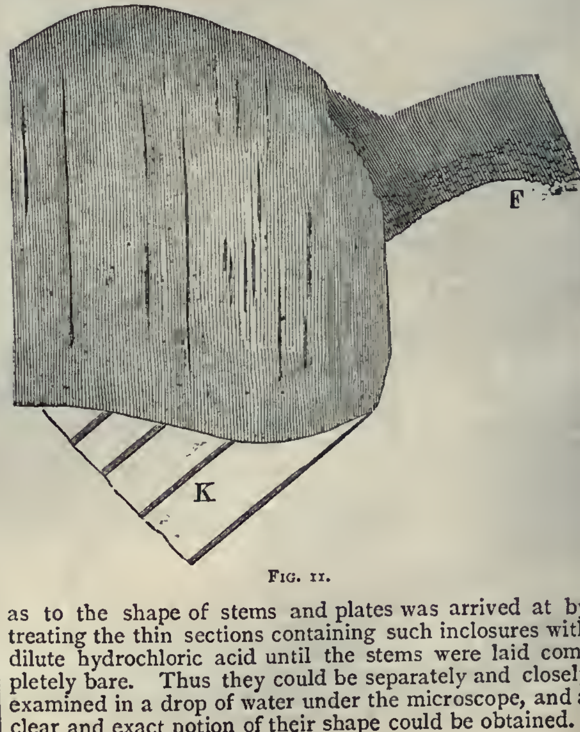

FIG. 11.

as to the shape of stems and plates was arrived at by treating the thin sections containing such inclosures with dilute hydrochloric acid until the stems were laid completely bare. Thus they could be separately and closely examined in a drop of water under the microscope, and a clear and exact notion of their shape could be obtained.

Figs. 6 to 9 represent several stems and plates isolated in the manner described and magnified 350 times.

Fig. 6 shows a bent and half tube-shaped stem; Fig. 7 a plate with two apertures; Fig. 8 a plate with alternate and parallel thicker and thinner parts; Fig. 9 a ramified stem of similar structure. In Fig. 6 the shape of the cross-section is indicated. The alternately thinner and thicker parts in Figs. 8 and 9 correspond to the lamellæ of the lime in which they laid imbedded, and therefore probably have their origin from these.

Now we have only to consider the fibres, which in many parts of the Eozöon, at the borders of the calcareous parts carrying the stems, surround the serpentine-like bands, but which in other parts pass right through the serpentine. In Fig. 5 these fibres are marked F, while the serpentine is designated by S. A very well-defined band of fibres is seen in Fig. 10 (magnified 200 times), between the serpentine S and a piece of lime in which obliquely ascending stems are cut right across at the surface of the section. O is a crystal of olivine in course of decomposition, and therefore no longer possessing sharp edges.

The fibres are imperfectly developed micro-crystals of chrysotile, which like olivine and serpentine consists of silica and magnesia. In many fibre-bands, with the application of strong magnifying powers, it is observed that the fibres are very small four-sided prisms. In Fig. 11, near F, such fibres are shown, magnified 500 times; to the left are long, less distinct, needle-shaped chrysotile crystals, besides lime (K).

(*To be continued.*)

NOTES

We have received from the U.S. Signal Office the monthly *Bulletins* for November and December, 1874, January, 1875, and January, February, and March, 1877. We hope shortly to begin, through the courtesy of General Myer, the regular publication of a map exhibiting the simultaneous monthly means in meteorology of the whole of the Northern Hemisphere. The immense value of such a publication to meteorological science we need not point out, and the enterprise of the U.S. Signal Office in working out and making public these data is beyond praise.

The Astronomical Museum established by Admiral Mouchez in the Paris Observatory may be considered as now complete. Besides the pictures of the principal celestial objects and portraits of the directors of the Paris Observatory, the hall contains a number of objects connected with astrology as well as astronomy, and a number of historical instruments, as the bar which was used for measuring the Peruvian degree, the similar instrument which was taken to Lapland by the Northern Commission; the pendulum used by Duperrey, and that used by Fraissinet for measuring the intensity of gravity in remote lands, the former being constructed by Fresnel; the bi-refracting prism used by Arago for his great optical discoveries, the portable meridian circle designed by Admiral Mouchez, &c., &c.

A solution of a problem which has lately acquired some celebrity, viz., *How to colour a map with four colours without colouring adjacent districts the same colour*, has just been obtained by Mr. A. B. Kempe, and will shortly appear at length in the *American Journal of Mathematics.* The fact that a map could be so coloured was stated by Prof. De Morgan to be well-known to map-makers, but no proof of the fact or means of solving the problem have hitherto, it is believed, been given. Some notion of the difficulty involved may be gathered from the fact that a very slight alteration in a map may render it necessary to recolour it throughout. Mr. Kempe's solution may be roughly described as follows:—He points out that every map must have a district in it with less than six surrounding it. This district he gets rid of by putting a patch over it which just projects over its boundaries, all boundaries which meet the patch being produced to meet in a point on the patch. A new map is thus obtained having one district less. This map must also have a district with less than six surrounding it which can be patched out in the same way. Continuing this process the map can at last be reduced to a blank sheet composed of overlapping patches. This can be coloured with a single colour. Stripping off the patches in the reverse order and colouring the districts as they are exposed, Mr. Kempe shows that whenever the 1, 2, 3, 4, or 5 districts surrounding a newly exposed one absorb all four colours, the colours can be rearranged in the map so as to reduce the surrounding colours to three, thus leaving a fourth for the exposed district. Thus successively taking off patches, rearranging the colours in the map, if necessary, and colouring the exposed districts, the whole map can be coloured. Mr. Kempe also shows *inter alia* that while the theorem is true in the case of globular surfaces as well as in that of maps, it does not hold in the case of such a surface as an anchor-ring.

We have received a copy of the second part of Mr. W. B. Hemsley's "Diagnoses Plantarum Novarum Mexicanarum et Centrali-Americanarum." We believe that the whole of the MSS. of the *Polypetalæ* of the botany of Messrs. Godman and Salvin's "Biologia Centrali-Americana," is now in the hands of the printer, and Mr. Hemsley is far advanced with the *Gamopetalæ*. The first part of the Polypetalæ will shortly appear. The publication of the Polypetalæ has been delayed, in order to include a very valuable collection made last year in the State of San Luis Potosi, Mexico, by Drs. Parry and Palmer.

A series of interesting experiments with the electric light commenced, by order of the authorities, at the School of Military Engineering, Chatham, on Thursday last. The experiments are for testing the relative qualities of the several inventions now in use in the Army and Navy, including Messrs. Wylde's invention (which has been fitted on board nearly all the larger ironclads in the Navy), Messrs. Siemens' invention, the Gramme light, and others. The experiments, it is expected, will last several weeks, and they will be carried out under the direction of Capt. Armstrong, R.E., instructor in telegraphy at the School of Military Engineering.

The Council of the Institution of Civil Engineers have recently made their annual awards, out of special funds bequeathed for the purpose, for approved original communications read and discussed at the weekly meetings during the past session, or printed in the "Minutes of Proceedings" without being read, as well as for papers submitted by students. From the Telford Fund medals and premiums have been bestowed on Messrs. G. F. Deacon, J. B. Mackenzie, J. N. Douglass, A. F. Blandy, E. Dobson, J. Price, J. E. Williams, G. W. Sutcliffe, E. Sang, W. G. Laws, and G. Higgin. The Manby Premium has fallen to Mr. J. P. Griffith. Miller Prizes have been adjudged to the following students:—Messrs. A. C. Hurtzig, R. H. Read, J. C. Mackay, and P. W. Britton.

The fourth marine excursion of the Birmingham Natural History and Microscopical Society to Falmouth, which extended from July 5 to 14, has proved a great success, and quite equalled, if not surpassed, the preceding ones to Teignmouth and the Island of Arran. A larger number of members than usual joined the party, which consisted of nine ladies and twenty-two gentlemen—a total of thirty-one. As hitherto the excursion was arranged so as to give facilities for the study of the marine zoology, botany, and geology of the district. For the former of these an admirable little steam tug, the *Albert*, was engaged. Land excursions were also arranged daily to interesting points, including the Land's End, the Lizard, &c. For the first time

the members had an opportunity of getting out into deep water of from forty to fifty fathoms, and a most interesting and valuable series of specimens was taken in all classes from diatoms up to fishes. The most noteworthy capture by the dredge in water of fifty fathoms off the Bay, was a specimen of the rare Alcyonarian zoophyte, *Virgularia mirabilis*. In the evenings the specimens taken were exhibited in the ladies' drawing room, some under the microscopes, under the superintendence of Mr. Marshall and Mr. Bolton. The botanists have not been idle, and nearly 400 species of flowering plants have been gathered, besides ferns of many species and varieties. A noteworthy circumstance connected with this excursion has been the kind assistance rendered by local naturalists, among whom are Mr. Howard Fox, the Rev. W. Rogers, Mr. Thomas Cornish, Mr. Tressidder, &c. Some valuable suggestions and encouraging remarks were also made in letters from eminent naturalists in special branches, viz., Prof. Allmann, Dr. Gwyn Jeffreys, Mr. P. H. Gosse, and Mr. H. J. Carter. On Thursday Mr. Saville Kent joined the party, accompanied the dredgings, and kindly rendered very valuable help. Full reports of the excursion will be presented to the Society in due course from the members who are going over the specimens; in marine zoology by Mr. Graham, the President, Mr. Saville-Kent, Mr. Wills, Mr. Trye, and Mr. Hughes; in botany by Mr. Baxenall and Mr. Morley; and in geology by Mr. Burman and Mr. Cotterell. Every effort was made for the comfort of the visitors by the obliging manager of the Falmouth Hotel, where the party took up their quarters, and the hon. sec., Mr. Morley, was indefatigable in his efforts to make the excursion successful. Not the least enjoyable part of the excursion was the really beautiful weather, which was fine and bracing during nearly the whole period. The twentieth annual Report of this Society speaks favourably of its progress, and the more active part taken by the members in its proceedings. Some consideration has been given to plans for utilising the energy of the Society in developing original research and knowledge of natural histology. Circumstances have interfered to prevent immediate action, but we hope that before long the Society will be able to carry its plan into execution.

AT the anniversary meeting of the Sanitary Institute of Great Britain the annual address was delivered by Mr. G. J. Symons, F.R.S., on "Water Economy." Mr. Symons, in the first part of his address, explained the circumstances which combined to render the small areas in the kingdom on which upwards of 75 inches of rain fell annually, of great national importance. Almost all these districts of heavy rain were districts of hard rocks, of steep slopes, and of sparse population. The first of these conditions insured the permanency of the physical geography of the district—the rocks being too hard to be washed away—and therefore the permanency of the rainfall; the second lessened evaporation, and sent the water rapidly into the streams or lakes; and the third tended to insure the purity of the effluent water. Having traced the water from the clouds to the earth, he next considered the effect of soil, crops, inclination of ground, &c., upon the water thus precipitated. He showed the necessity for modifying our customs and laws respecting rivers and watercourses, &c., in conformity with the advance of civilisation and the increasing population of the country. He recommended that the entire administration of streams should be under a single direction, which should see to all questions of drainage, sewerage, canalisation, motive power, and water supply. Such new works as were required promptly should only be authorised subject to their reverting to Government in fifty or a hundred years. All other hydraulic works should be undertaken, or at all events supervised, by a Government department, so as to insure the greatest possible public benefit and not merely that of an individual town.

MR. R. ANDERSON, F.C.S., whose paper on Lightning Conductors and Accidents from Lightning attracted considerable attention at the last meeting of the British Association, has for some time been engaged on a large work treating the subject from a scientific, practical, and historical point of view. The book is now nearly ready, and will be published in a few weeks.

WE have received from Mr. William George of Park Street, Bristol, the first four numbers of an interesting catalogue of works referring, *inter alia*, to geography, geology, chemistry, and other branches of science. The catalogue displays a considerable knowledge of the bibliography of these subjects, and would, no doubt, interest many of our readers.

AMONG Mr. Murray's announcements are: "The River of Golden Sand; a Narrative of a Journey through China to Burmah," by Capt. Wm. Gill, R.E.; "A Lady's Life in the Rocky Mountains," and "Japanese Letters," by Miss Isabella Bird; "A Sketch of the Life of Erasmus Darwin," by Dr. Krauss, translated from the German, with a preliminary notice, by Charles Darwin, F.R.S.; "Metallurgy, Part V., Silver and Part of Gold," by Dr. J. Percy, F.R.S.

THOSE of our readers interested in India may be glad to know that Mr. Quaritch has on sale the second edition of Balfour's monumental Cyclopædia of India.

M. W. DE FONVIELLE writes:—"On July 9 I made an ascent at Douay in a small balloon, at 5.30 P.M., with a strong west-south-west wind; velocity, 1 kilometre per minute. The temperature varied from 12° to 14° C. according to the exposure, and the altitude from 900 to 1,300 metres. From 800 to 1,000 were small floating clouds of irregular shape, not more than 100 metres in altitude and 200 metres in transverse dimension, but very dense, obviously formed with pure water, without any snowy matter. We observed at six different times the white rainbow, or Ulloa Circle, at the superior surface of this cloud. This dispels the notion, published in so many text-books, that it is seen only on icicles. There were three circles—interior blue, medium yellow, and exterior red. I had not a sextant for measuring the diameter, which I suppose was not more than 25 to 30 degrees for the exterior circle, somewhat less than the little halo, and in all cases about the same, irrespective of the distance of clouds. It was, of course, seen opposite the sun. The interior part was quite silvery white, being merely reflected light from the sun. The shadow of the car, travellers, and balloon was seen in the centre with angular dimensions varying according to the distance of the clouds. The shadow was sometimes projected outside the luminous circles, being too large to be included. Once we saw distinctly a luminous circle developing round the balloon, and we had two coloured images at once. The balloon phenomenon did not last long enough to be carefully observed; it appeared less distinct. I recollect only the reddish part of it, but we are both certain of its appearance. I suggest the acceptance of the explanation given by Bravais of the white rainbow, that it is produced by the reflection of the sun's rays on the surface of small vapoury vesicles, composed of a little quantity of air imprisoned by a shell of water. I noted also a curious optical illusion of a kind which was indicated to me by Mr. Coxwell a few years ago. When the clouds were at some distance they appeared almost at the same level, and I was under the impression that the balloon was ascending as they were passing under the car at some distance below. But the barometer and other circumstances proved we were keeping almost a perfect vertical equilibrium, and travelling in a horizontal direction."

W. B. F., writing from Point-of-Air, North Wales, on the 14th inst., states that an earthquake was observed there that morning at 1.5 A.M. The direction of the undulation appeared to be from a little to the east of south to a little to the west of

north. The movement of the earth was plainly felt by several persons in the neighbourhood. Previous to the shock the night was clear, warm, and calm, with a slight air from the south-west; twenty minutes after the shock there was a thunderstorm, accompanied by very heavy rain.

FROM a statement in the House of Commons by the Under-Secretary of State, it seems that the distribution of the Indian Museum collections has not yet been determined on, and is the subject of investigation by a committee in communication with the authorities at the British Museum, South Kensington, and Kew Gardens. The main object which is expected to be gained by this step is the increased utility of the collections to the public. The Economic Section, for instance, it was stated, could be maintained and perfected with great public advantage in the experienced hands of Sir Joseph Hooker at Kew, where he already has a far better collection of similar objects; while as regards the zoological, ethnological, and art collections, their transfer to departments where they will be more generally seen and appreciated, seems better than to retain them in a museum which, somehow or other, does not attract visitors. The fact that 9,000*l.* a year will be saved to the Indian revenues, may not have been without weight in deciding to break up the Museum.

THE *Daily News* New York correspondent telegraphs as follows :—"Mr. Edison has partially overcome the obstacle to his electric light offered by the high price of platinum. His lamps, instead of costing several dollars apiece, as at first, can now be made of an alloy of platinum with inferior metals, so as to cost only fifty-six cents. He announces that he can now produce the spiral coil for incandescence at a price which all who use gas can easily afford, and that his efforts to find platinum are only induced by the desire to reduce the cost of burners still further."

No. 27 of the *Journal* of the Society of Telegraph Engineers contains an important paper, by Col. Bolton : "Some Historical Notes on the Electric Light," consisting of abstracts from all the English patents on dynamo- and magneto-electric machines and on electric lights, classified and arranged in subdivisions according to the special class feature of each form of machine or lamp. From these abstracts it will be seen that several of the so-called new inventions on this subject that have been attracting so much attention of late are really inventions of long ago.

IN recent researches (described to the Vienna Academy) on the specific viscosity of liquids and its relation to chemical constitution, Herr Pribram and Herr Handl have observed (1) that the substitution of Cl, Br, I, and NO_2 for H in a molecule, caused, in all cases examined, an increase in the time of flow (through a capillary tube); (2) that this increase was least on substitution of Cl, and more, successively, in those of Br, I, and NO_2; (3) that for the absolute value of increase of the time of flow, not only the quality of the element introduced, but also its position in the molecule, is a determinant.

ACCORDING to Prof. Du Bois Reymond, grave sounds should be more weakened by telephonic transmission than acute sounds (causing an alteration of *timbre*), but all sounds, whatever their pitch, suffer a retardation of a quarter of a wave. On the other hand Prof. Helmholtz, by a theory apparently more complete, finds that all sounds are weakened nearly in the same proportion, and that the difference of phase introduced must be very small. M. Koening has recently made experiments with a view to decide the question. He substitutes two tuning-forks, A and B, for the membranes of two associated telephones, and vibrates A with the bow; at once B enters into vibration, and one may, either by observing successively with an optical comparing instrument, the vibrations of A and B, or by arranging A and B as in the well-known experiment of M. Lissajous for composition of rectangular vibratory movements, measure the difference of phase of the tuning-forks, which is found exactly equal to a quarter of a wave-length. An experiment on complex sounds was made by changing one fork Ut_1 for fork Ut_4 so as to produce simultaneously the sounds 1 and 8 before the bar of a telephone. The difference of phase was still found equal to a quarter of a wave. Thus Du Bois Reymond's view is more in accord with experiment than that of Helmholtz.

ACCORDING to Herr Kohlrausch (*Ann. der Physik*, No. 6) well-defined tones may be produced in a simple way by only two impulses. Place two fingers of the hand loosely together, so that the end of the nails are about on a level, and then tap gently on the table, the proper tone of this having been deadened as much as possible by means of books, or sitting on it, or otherwise. It will be readily felt that the two fingers seldom strike quite simultaneously, and with some attention one may hear (best if the tapping be repeated twice or thrice in a second) in addition to the noise, of indeterminate pitch, a very bald tone of pitch varying at first with the position of the fingers, but which, after a little practice, one can approximately fix. It is also possible to give a musical interval by tapping twice with the fingers differently adjusted; Herr Kohlrausch says he has often perceived differences of pitch to the extent of a semitone. Within the interval 15 : 16, then, the tones of only two impulses can be accurately determined. Tapping with only one finger-nail these tones entirely disappear; and one may therefore easily learn to hear them by tapping alternately with the one and with the two fingers.

IN a recent paper to the Belgian Academy M. Renard endeavours to fix the distinctive characters of calcite and dolomite in rocks which contain these two elements associated in microscopic individuals. After showing that the characters on which the distinction has been established hitherto are not satisfactory, he substitutes the character which dolomite has of appearing nearly always with the form of the original rhombohedron, whereas calcite never, one may say, affects this crystalline form. It results from his observations that the dolomites which do not belong to the normal type must be considered as mechanical mixtures of dolomite and calcite, and not as combinations in which the excess of one of the two constituent bases must be interpreted according to the laws of isomorphism. M. Renard supports his determinations by chemical researches under the microscope, and, in concluding, he points out that in the case of several dolomitic rocks of carboniferous limestone, the dolomitisation is due to an action posterior to the sedimentation of the calcareous elements.

WILLUGHBY, not Willoughby (as printed in last week's NATURE) is the name of the new society for reprinting scarce ornithological works, which takes its name from Francis Willughby, the pupil and patron of John Ray, who first edited and then translated his "Ornithologiæ Libri tres," besides his ichthyological works.

THE International African Association have just published a note by Dr. Dutrieux, of the Belgian African Expedition, on the subject of a parasitical cutaneous affection which he has had opportunities of observing during his journey. The parasite especially attacks oxen, whence it is called *founza ia ngômbé* (ox-worm). The negroes suffer a good deal from it, and it appears to burrow into different parts of their feet. When it is extracted, in consequence of their always going barefooted, they get very painful ulcers, which Dr. Dutrieux says are exceedingly difficult to cure.

THE new number of the *Indian Forester* contains a paper of much interest on the Banda Forests, and the continuation of another on the function of the pines and the larch in the production of soil. There is also a letter which furnishes some curious notes

on the coppicing powers of certain trees in dry and arid climates.

THE *Annual Report* of the Society of Arts for 1878-9, shows, as might be expected, that during the past session, a vast amount of good and useful work has been done under its auspices. As to the material condition of the Society the report is favourable, notwithstanding the badness of the times.

THE Report of the Auckland (N.Z.) Institute for 1878-9, speaks of the steady progress of the Society, and the increasing interest manifested by the public in its operations. Several valuable papers on New Zealand natural history have been read.

WE have received a number of little Guides for Science Teaching, issued by the Boston (U.S.) Society of Natural History. The enterprise is creditable to the Society, and the "Guides" seem to us to be handy and trustworthy. Some of them are reprints and second editions. They are—"About Pebbles," by Alpheus Wyatt; "Concerning a Few Common Plants," by G. L. Goodall: "Commercial and other Sponges," by A. Wyatt; a reprint of Mrs. Agassiz's "First Lesson in Natural History;" "Common Hydroids, Corals, and Echinoderms," by A. Wyatt. The last three are very fully illustrated.

WE have received from Mr. J. T. Peacock, the eminent grower of succulent plants, a list of the plants cultivated by him; these comprise cacti, agaves, yuccas, sempervivums, euphorbias, and in fact all plants of a succulent or fleshy nature, many of which have hitherto been much neglected by cultivators. The extent of Mr. Peacock's collection may be judged from the fact that at the present time portions are contained at Sudbury House, Kew, the Alexandra Palace, and the Botanical Gardens, Regent's Park. For the purpose of making this class of Plants more generally appreciated among amateurs Mr. Peacock intends sending the printed list to applicants who send an addressed halfpenny wrapper to Sudbury House, Hammersmith.

THE *Allgemeine Zeitung* reports important anthropological discoveries in Moravia. Excavations have been going on for some months back under the direction of Herr Carl Maschka, a specialist in these subjects, in the Shipka and Tschertowa Dira caves, near Stramberg. The discoveries, it is stated, have been made in layers, carrying the investigator back step by step to the palæolithic age. Stone and bronze weapons, with bones of a variety of animals belonging to different periods, appear to have been found in large numbers.

OWING to the great cost and often very inferior quality of gas, the *Colonies and India* states that for street lighting the electric light is coming into favour in many parts of Australia, and in South Africa particularly; and when the problem of subdividing the light for use in small houses is satisfactorily solved, it will find a wide field in which it can establish itself more rapidly than will be the case in England.

A JAPANESE paper states that some chemists have discovered a vein of silver at Yuigahara, in Kioto-Fu. The water of a pond in the neighbourhood being discoloured, their curiosity was excited as to the cause, and a search for minerals in the vicinity resulted in the discovery mentioned.

FROM the Third Annual Report of the Burton-on-Trent Natural History and Archæological Society, it seems to be in a prosperous condition. It forms one of the Midland Union of Natural History Societies, and the work it is doing is on the whole creditable.

THE additions to the Zoological Society's Gardens during the past week include two Crested Porcupines (*Hystrix cristata*) from West Africa, presented by Mr. Moses Boyle; a Black-winged Peafowl (*Pavo nigripennis*) from Cochin China, presented by the Hon. A. S. G. Canning, F.Z.S.; a Buff-backed Egret (*Ardea russata*), European, six Small-scaled Mastigures (*Uromastix microlepis*) from Busreh, presented by Capt. Burke, s.s. *Arcot*; a Gold Pheasant (*Thaumalea picta*) from China, presented by Mr. J. E. Liardet; two Common Barn Owls (*Strix flammea*), European, presented by Mr. R. A. Baldwin; an Indian Python (*Python molurus*) from India, a South American Rat Snake (*Spilotes variabilis*) from South America, presented by Mr. George Billett; two Elliot's Guinea Fowls (*Numida ellioti*), four Vulturine Guinea Fowls (*Numida vulturina*) from East Africa, deposited; a Striped Hyæna (*Hyæna striata*) from India, a Yellow-footed Rock Kangaroo (*Petrogale xanthopus*), four Black Swans (*Cygnus atratus*) from Australia, two Balearic Cranes (*Balearica pavonina*), four Rose-ringed Parrakeets (*Palæornis docilis*) from West Africa, two Siamese Pheasants (*Euplocamus prælatus*) from Siam, a Darwin's Pucras Pheasant (*Pucrasia darwini*) from China, purchased; a Japanese Deer (*Cervus sika*), born in the Gardens; three Australian Wild Ducks (*Anas superciliosa*), a Spotted-billed Duck (*Anas pœcilorhyncha*), six Rosy-billed Ducks (*Metopiana peposaca*), bred in the Gardens.

HOLLWAY'S NEW APPLICATION OF RAPID OXIDATION BY WHICH SULPHIDES ARE UTILISED AS FUEL[1]

THIS process has for its object the utilisation of the heat generated by the rapid oxidation of certain mineral substances, which have not hitherto been used as sources of heat for smelting operations. The heat thus obtained is employed in the reduction of the furnace charge, which may be composed partly of sulphides and partly of siliceous ores. A current of air is forced through molten sulphides, by which means they are very rapidly oxidised. Great heat is thus developed, rendering the process of smelting a self-supporting operation; therefore no extraneous fuel is required, excepting that employed in raising steam for the blowing engines; where, however, water power is available, steam can be dispensed with, in which case all the carbonaceous fuel necessary for the operation is a little coke to start the furnaces, which stands in the same relative position to the ores as wood does to coal in the lighting of an ordinary fire.

It is well known that pyritous minerals are readily combustible, but the best means of utilising the heat-producing property of metallic sulphides is not so apparent as would at first sight appear. Of these sulphides only iron pyrites is sufficiently combustible at a low temperature to burn in the open air, the mass being raised to the temperature at which the oxidation takes place solely by the union of sulphur and iron with atmospheric oxygen. In Spain there are numerous deposits of poor cupreous pyrites, and the Rio Tinto and Tharsis Companies annually treat, at their mines, about one million tons for the extraction of copper only, which does not average 2 per cent. The process employed consists essentially in roasting the pyrites in heaps in the open air, dissolving out the copper from the roasted material, and precipitating it from the solution by means of iron. These operations extend over several months; any gold or silver contained in the ore is lost, and the iron and sulphur are also wasted. The sulphur passes into the air as an obnoxious and annoying gas, desolating the country for miles around the works.

From the earliest ages, carbon has been considered a necessity in all metallurgical operations. The first reduction of metals by means of carbon forms a connecting link between the age of stone and the commencement of civilised art. It is well known that carbon burns at widely varying temperatures, as, for example, in our bodies, in a common coal fire, or in a furnace. A great deal of thought has been devoted to the subject of economising carbonaceous fuel, and great advances have been made in this direction; yet the expenditure of coal or coke necessary, say, to melt a given quantity of metal, still far exceeds the theoretical limit. The main causes of this discrepancy may be accounted for as follows:—

1. Only part of the oxygen of the air passing into a furnace, acts on the material to be burnt.

2. The oxygen is not brought in contact with the combustible matter with sufficient rapidity, to obtain the necessary temperature for the operation.

3. Gases pass off hot and unburnt. These are now, however, frequently utilised.

[1] Communicated by Mr. Hollway.

There is one metallurgical operation in which the first two sources of loss are avoided, viz., "Bessemer's," where, by blowing air through molten crude iron, a very high temperature is attained by the combustion of small quantities of carbon and silicon contained in the crude iron; this is, however, not the case in the process of puddling, where the oxidation is spread over a considerable period of time, although the same constituents are frequently burnt in similar proportions. But even in the Bessemer process the carbon is only half burned, and a large amount of heat escapes with the carbonic oxide and nitrogen.

When, however, thin streams of air are forced through molten sulphide of iron, lying on a tuyère hearth, a high temperature is produced by the perfect combustion which ensues in the midst of the sulphides, and no unburnt gases, excepting nitrogen and sulphur vapour, escape from the surface of the molten mass. The hot nitrogen and sulphurous acid may be caused to act upon iron pyrites and other mineral matter, and when pyrites is thus heated, an atom of sulphur held in feeble combination is in great part expelled, and thus is obtained molten protosulphide of iron, which is subsequently burnt by the oxygen of the air driven in at the lower part of the furnace, thereby producing the heat necessary for continuing the operation. The process may be defined as a system of fractional oxidation, in which the numerous constituents of a complex furnace charge can be separated from each other and concentrated in different parts of the apparatus, the heat necessary for the operation being obtained by the combustion of a portion of the less valuable constituents.

The principal ores of all our ordinary heavy metals, except manganese and tin, are sulphides. Iron, although largely occurring in an oxidised form, is abundantly found in combination with sulphur; and bisulphide of iron, or iron pyrites, is an example of sulphurous and combustible minerals. Associated with iron and sulphur in iron pyrites are invariably found small quantities of other metals, notably cobalt, nickel, copper, silver, gold, lead, zinc, and arsenic. Of these, zinc is almost as combustible as iron itself, while lead and arsenic readily volatilise as sulphides, and cobalt, nickel, and copper are distinctly less readily oxidisable than iron, while silver and gold do not oxidise under these conditions; hence, in supplying air to such material, the iron is the first of the elements to suffer oxidation, so that if the oxidation be arrested before the whole of the iron has been burnt, the cobalt, nickel, copper, silver, and gold present will be found in the unburnt portion. This principle finds a parallel in the Bessemer process of treating pig-iron for the manufacture of steel, where a current of air is caused to bubble up through a bath of molten crude iron, [the silicon is first oxidised, and is closely followed and to a great extent accompanied by the carbon, and no large amount of iron suffers oxidation, until the whole of the silicon and carbon have been burnt out of the molten material.

The experiments made at Messrs. Cammell's works, at Penistone, in a Bessemer converter, have proved that by blowing air through molten sulphide of iron, the iron and a portion of the sulphur are oxidised, and if the oxidation is arrested before the combustion of the iron is complete, a heavy matt or regulus is obtained, which contains but a small proportion of the iron of the ore, but practically the whole or the greater part of the copper and other less oxidisable metals. In one of these experiments the molten sulphides were run into the converter from a cupola, in which they had been previously melted, and the temperature was kept up until the operation was discontinued, viz., for a period of ten hours, without the use of any carbonaceous fuel, the heat being entirely derived from the oxidation of the iron and a portion of the sulphur of the lumps of pyrites, which were continuously thrown into the mouth of the converter. A Bessemer converter being unsuited for the collection of the gaseous products, the later experiments have been made in a series of cupola furnaces belonging to Messrs. John Brown and Company, Limited. These experiments have proved the possibility of obtaining a valuable regulus, a slag nearly free from copper, and a considerable quantity of crude sulphur. M. Pourcel, the well-known chemist of the Terrenoire Company, has also made some very interesting experiments, having treated by this method a cupriferous sulphide of antimony containing lead and zinc, using heavy spar and silica as fluxes; he obtained a regulus containing the whole of the copper in the form of sulphide, a slag of light specific gravity, and the lead, zinc, and antimony as two separate sublimates which were condensed in different parts of the apparatus, owing to the superior volatility of sulphide of lead over the oxides of antimony and zinc. In the experiments at Penistone and at Sheffield a cold blast of air was employed, and the gases which passed from the converter or furnace into the open air, carried away with them a large amount of heat. In practice, however, it would be economical to employ a hot blast, which could be heated by the waste heat from the escaping gases. It is remarkable that the least valuable metals, viz., iron and zinc, generate by their combustion the largest quantities of heat.

The process may be employed for the reduction of even the more volatile metals; for example, Mr. A. H. Allen, of Sheffield, has thus obtained metallic antimony simply by the oxidation of sulphide of antimony. It is well known that sulphide of lead reacts upon oxide of lead with the production of metallic lead and sulphurous acid. If, therefore, a limited amount of air is blown into molten sulphide of lead, the oxide thus formed in the lower part of the furnace will, in passing upward, come in contact with the hot sulphide of lead, and metallic lead will result, with the evolution of sulphurous acid. The furnace having a quiescent hearth below the tuyères, the metallic lead will collect there, and can be from time to time withdrawn. A limited amount of air must be employed, because if it is driven in too quickly, the sulphide of lead will rapidly distil off. In thus treating argentiferous lead ores, the silver (and gold if present) would be found with the first metallic lead reduced. When thus treating galena the furnace should have a basic lining.

The process is peculiarly suitable:—

1st. For the treatment of metalliferous substances which cannot be advantageously treated by other processes. For the extraction of sulphur by distillation, and simultaneously for the concentration and separation of cobalt, nickel, copper, silver, and gold from minerals in the form of metallic regulus; while lead, zinc, antimony, arsenic, &c., accrue in the sublimates.

2nd. For the treatment of complex ores, for example—Grey antimonial copper ores, such as those experimented on by M. Pourcel. Ores similar to those worked at the well-known Bottino Mines, Seravezza, in the Italian Apennines, which contain thirteen or fourteen heavy metals, including silver and lead, for which latter alone they have been worked for centuries. The blende of lead mines, in Derbyshire termed "muck," usually thrown away by the miners, because the large quantity of lead with which it is associated renders the zinc obtained from it worthless.

3rd. For the treatment of auriferous and argentiferous pyrites. It is well-known that in practice it is not possible to obtain the whole of the gold from pyrites by amalgamation with quicksilver, because the presence of sulphur and arsenic sickens and flours the mercury, whereas by fusion the whole of the silver and gold present is obtained.

4th. For the treatment of pyrites containing even only small percentages of cobalt, nickel, and copper, which are thus concentrated into a rich regulus, whereas this result is now only obtained by very tedious processes of alternate roasting and reduction. Such ores containing 10 per cent. and even 12 per cent. of copper exist in South America and many other parts of the world, but are not at present capable of economic treatment, owing to the difficulty of obtaining a sufficient supply of cheap fuel. The process can also be advantageously applied to the treatment of richer ores of copper such as are at present smelted at Swansea.

5th. For the treatment of poor lead ores. If such ores are added to a furnace charge of cupreous pyrites, the silica they contain will be utilised and combine with the resulting oxide of iron to form slag, the galena will be volatilised and be recovered as a sublimate, while any silver present will enrich the regulus. At present, by a costly process of crushing and washing these ores, the galena is concentrated, although a large proportion is left with the *débris*, and passes with the water into the streams, rendering the existence of fish in such waters impossible. The water power now used for washing the ore could, in many cases, be employed for producing the blast.

When thus treating cupriferous iron pyrites, four products are obtained:—

1st. A matt or regulus containing from 30 to 50 per cent. of copper, any traces of cobalt, nickel, silver, or gold the ore may contain, the rest of it being iron and sulphur; it has a specific gravity of 4½ to 5.

2nd. A slag consisting of silicate of iron from the resulting oxide of iron combined with the siliceous matters contained in the ore and the fluxes added.

3rd. Sublimed sulphur, more or less mixed with volatile compounds of lead, zinc, and arsenic.

4th. Sulphurous gases, consisting mainly of sulphurous acid and nitrogen.

The regulus closely resembles, and will replace, the coarse metal of the Swansea copper process, which is now only obtained at considerable cost of labour, time, and carbonaceous fuel. When, however, sulphides of iron and copper present in the bath are treated continuously by a blast of air, a point is at length arrived at when the whole of the iron is oxidised, and the regulus in the bath consists of sub-sulphide of copper. If, now, a limited supply of air is introduced, the copper is reduced to the metallic state with the evolution of sulphurous acid.

The slag obtained in the Penistone experiments was essentially silicate of iron, containing about 50 per cent. of iron and 29 per cent. of silica. It had a density of about 3 8 to 4, and was in composition somewhat allied to the copper-smelter's ore furnace slag and to the tap-cinder of the iron-puddler. By the addition of calcareous materials, the specific gravity of the slag is so reduced as to cause it to separate readily from the regulus which collects below it. In one of the later experiments, when lime was used, the proportion of copper lost in the slag was very small. This is, of course, a most important point, for when dealing with ores containing but little copper, the presence of even a small percentage in the slag means the loss of a considerable proportion of the copper present. These slags can be utilised for the manufacture of steel, being practically siliceous iron ores free from phosphorus, and their reduction in a blast furnace can be profitably effected, as the proportion of iron present is high as compared with the weight of the material; indeed, it may be possible to reduce them while in a molten state.

By re-subliming the crude sulphur, it can be freed from all impurities except arsenic, and at the works of Messrs. John Hutchinson and Co., Widnes, this is eliminated by means of polysulphide of calcium.

As a certain proportion of the sulphur of the minerals suffers combustion, the resulting sulphurous gases contain from 14 to 15 per cent. of sulphurous acid, and hence the proportion of sulphurous acid to nitrogen is nearly identical with that of the gases produced by roasting pyrites in the kilns employed by vitriol manufacturers, and can, therefore, be used with equal advantage for the production of vitriol in leaden chambers. This appears to be the simplest solution of the great problem how to smelt copper without causing a nuisance to the surrounding neighbourhood, although a similar result might be obtained by collecting and liquefying the sulphurous acid.

The more incombustible materials it is found practicable to employ without too great a loss of temperature, the wider will become the application for the process; for there are many ores, including silicates and carbonates, containing metals in the form of oxides, which might be conveniently smelted by mixing them with a sufficient proportion of pyritous ores to effect their reduction; in fact, one of the chief practical questions connected with this process is how far it may be trusted to effect the smelting of ores or furnace charges containing comparatively moderate proportions of sulphides. It is evident that it will almost entirely obviate the necessity for using carbonaceous fuel, at least as far as the production of a regulus is concerned, and consequently the localities in which smelting operations may be advantageously carried on are thus greatly multiplied. One of its chief merits is that it is equally applicable with comparatively little extra cost in the working, to very poor and very rich ores, for however small the resulting regulus, it will contain nearly the whole of the cobalt, nickel, copper, silver, and gold present in the furnace charge, while any lead, zinc, antimony, and arsenic will be obtained as sublimates.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

THE authorities at Owens College, Manchester, and of the Yorkshire College of Science, Leeds, have already taken the initiatory steps for preparing a constitution of the new University for the North of England, for which a charter has recently been granted. The Council of the Owens College have appointed a committee of their body, and on Friday they met in conference at the college in Manchester, with representatives of the Council of the Yorkshire College of Science, for the purpose of considering a draft constitution for the new institution. The basis of the deliberations of the conference is to be found in the series of suggestions contained in an appendix to the memorial which was presented to the Privy Council some time ago, but various questions will come before the meeting for consideration, including the power of granting degrees to women and the better representation of the graduates and the teaching staff upon the Board of Governors. Considerable progress was made on Friday in preparing suggestions for a draft of a proposed charter, though each of the clauses was very fully discussed before adoption. When the conference has completed its task it will report to the Council previous to the scheme being submitted to the Law Officers of the Crown.

MR. W. N. HARTLEY, of King's College, London, has been appointed Professor of Theoretical and Practical Chemistry in the Royal College of Science, Dublin, and enters upon his duties at the beginning of the October term.

THE following students have passed the examinations which entitle them to the distinction of "Associate of the Royal School of Mines":—In the Mining and Metallurgical Divisions: Mirza Mehdy Khan. In the Mining Division: W. E. Benton, A. G. Charleton, A. D. Ellis, E. N. Fell, H. B. Statter, H. Strickland. In the Metallurgical Division: W. B. M. Davidson, A. H. Fison, F. W. Grey, E. Halse, E. W. Harvey, Malcolm Hill, J. H. Lucas, Walter Marsh, A. Gordon Salamon. The two Royal Scholarships of 15*l*. each have been awarded to J. J. Hood and J. F. Wilkinson. The Royal Scholarship of 25*l*. has been awarded to Ralph G. Scott; the De la Beche Medal for Mining to A. D. Ellis; and the Murchison Medal for Geology to B. Mott.

SCIENTIFIC SERIALS

American Journal of Science and Arts, June.—Reviewing what is now known of extra digits in the feet of the modern horse Prof. Marsh says the instances fall naturally into two groups: the first comprising simply cases of reduplication (like that of the occasional extra-finger in the human hand), not satisfactorily explained as yet; the second includes cases where a true digit is formed, the component bones in normal position and relation, and such instances seem clearly due to reversion to some ancestral type. Extra digits appear more frequently on the fore feet than the hind feet (as a study of fossils would lead one to expect), and more frequently on the inside of the main digit, the outer splint remaining rudimentary (this, again, is opposed to the general law of reduction in the ungulate foot).—Mr. Sargent's paper on the forests of Central Nevada has been elsewhere referred to, and we further note that Prof. J. C. Draper writes on the dark lines of oxygen in the solar spectrum on the less refrangible side of *G* (in the regions about λ 4317 and λ 4319); Mr. Christy seeks an answer to the question "Are cinnabar deposits produced by sublimation, or are they deposited from solution?" and concludes that they are the immediate result of the action of solutions of alkaline carbonates containing also alkaline sulphides; Mr. Hodges suggests a new absolute galvanometer.—Mr. Sawyer contributes a first catalogue of radiant points of meteors (from observations at Cambridge during the last two years); and Maria Mitchell notes on the satellites of Saturn.—A recent paper published in Brazil, by Mr. Derby, on the geology of the Lower Arizonas, is summarised by Mr. Rathbun.

Journal of the Franklin Institute, June.—We note here the following:—Peaucellier's compound compass and other linkages, by Prof. Marks.—Some experiments on alloys of silver with embrittling metals, by Mr. Outerbridge.—Phosphorus in coal, by Mr. McCreath.—On the determination of silicon in pig-iron and steel, by Dr. Drown.

Reale Istituto Lombardo di Scienze e Lettere. Rendiconti. Vol. xii. fasc. xi.-xii.—On an integral formula, by Prof. Beltrami.—On tetrahedral systems, by S. Aschieri.—Atrophy and degeneration, by Prof. Sangalli.—On a parasite Colothurnia of the branchiæ of our crabs, by Prof. Maggi.—A microphyte on Hesperideæ, by Dr. Cattarneo.—The infirmity of Torquato Tasso, by Prof. Conadi.—A new bird for the Lombardy fauna, by Prof. Pavesi.—On the centre of forces in the plane, by Prof. Bardelli.—On the cortical iridian centre in birds, by S. Ortel.—New series of researches on the pelagic fauna of the Italian lakes, by Prof. Pavesi.

SOCIETIES AND ACADEMIES

London

Royal Society, June 19.—"Preliminary Note on a New Tide-predicter." By E. Roberts, F.R.A.S. (*Nautical Almanac Office.*) Communicated by Prof. G. G. Stokes, M.A., Sec. R.S., &c.

The Indian Survey Department having undertaken the superintendence of tide-registration around the whole sea-board of India and at the port of Aden, and also the reduction of the observations by the method of harmonic analysis, with the view to the prediction of the tides for the whole of the ports, it became a matter of necessity, in order to save the large outlay which the numerical operation of their prediction would have involved, that an instrument should be constructed to delineate the predictions.

Accordingly, on the recommendation of the Surveyor-General of India, I was desired to design, and to undertake the construction of, an instrument to include a sufficient number of tide-components to predict the Indian Ocean tides with all the accuracy necessary for practical purposes.

The present machine is the outcome of the recommendation.

The instrument combines the following twenty tide-components:—

The mean lunar semidiurnal;
The first and second overtides of the mean lunar semidiurnal;
Two *elliptic* lunar semidiurnal;
Two *evectional* lunar semidiurnal;
One *variational* lunar semidiurnal;
The mean solar diurnal;
The mean solar semidiurnal;
The lunisolar semidiurnal;
The lunisolar diurnal;
The lunar diurnal;
The solar diurnal;
One lunisolar elliptic diurnal;
One lunar elliptic diurnal;
One compound (Helmholtz) lunisolar semidiurnal;
One compound (Helmholtz) lunisolar quarter-diurnal;
The solar annual; and
The solar semiannual.

Strictly speaking, there is no sensible astronomical tide-component of twenty-four mean-solar hours' period, but for the purposes of prediction it is necessary to include such a term, a very regular and sensible result of this period being obtained in the analysis, due probably to wind or temperature. The same remark applies partially to the solar annual and the solar semiannual, the theoretical tides of these periods being very small; the analysed results, however, are of considerable value, being due probably to the effect of rainfall and the regularity of the monsoons. These three components should, therefore, be regarded more as meteorological than astronomical.

The stipulation that the scale for heights should be one inch per foot range for Bombay necessitated a recording barrel of some 18 inches at least; the actual length adopted for the instrument, however, is 22 inches. The delineation of the curves on such a large scale rendered necessary some modification of the system of excentric pulleys, as fitted on the tide-predicter of the British Association. It was at first contemplated to fit parallel slides only to the larger of the tidal components; the whole of them have, however, been so provided.

The chief difficulty in the construction of the machine is the finding, within reasonable limits, of proportions which shall represent with sufficient accuracy the periods of the several components, in order that the machine may be used for a considerable period of prediction—say, for twelve months. Very great success has been attained in this respect in the present instrument. For instance, the error of the period of the chief component (the mean lunar semidiurnal) relatively to the mean solar semidurnal is inappreciable during a whole year's predictions, amounting to about $0^{\circ}\cdot10$ only in a period of fifty years. The largest deviation from strict accuracy is $0^{\circ}\cdot37$, after a run representing twelve months. This is, however, of one of the very small components, and insensible in its results. This part of the design may be therefore regarded as practically perfect.

Each component is provided for setting with a crank, in which a sliding piece is fitted, carrying a steel guiding-pin. The guiding-pin is thrown out by means of a fine-cut screw and micrometer head. An improved parallel slide, carrying a pulley, is also fitted to each component. The guiding-pin works between two parallel adjustable steel jaws at the back of the pulley frame. The pulley frame is fitted with a balance-weight, so that its centre of gravity is in a vertical line through the pulley's axis. The whole slide is counterpoised by a cord and weight, passing over pulleys, in order to relieve the guiding-pin of all strain and to prevent wear. The steel bar of the pulley slide moves freely in two guides drilled out nearly their entire length to reduce the touching parts to a minimum. The other side of the pulley slide is kept in position by a projecting fork or guide, travelling with freedom along a narrow flat brass bar. Both the brass bar guide and the steel rod guide are divided to millimetres; the brass bar for approximate, and the steel rod for the accurate, adjustment of the throw of the crank-pin, for which purpose the upper guide of the steel rod is furnished with a vernier. The milled head of the micrometer-screw is also divided and may be used with the divisions on the brass bar guide. The pulley frame is movable on its steel rod, for the purposes of the perfect adjustment of the pulley about the centre of motion of the axis of the crank.

The axis of the crank carries behind the main plate a fine-toothed wheel, fitted on a slotted cone, with a milled nut for clamping the wheel on its axis. The toothed wheel is driven by an endless screw, carrying a bevelled wheel, which is itself driven by another bevelled wheel on one of the four main axes of the machine. The endless screws and main axes are fitted with counter pivots.

At the back of the machine are fitted the setting dials. Each dial is toothed round its outer edge and movable round its centre by a pinion for adjustment. The axis of the component projects through the setting dial, and carries a steel pointer for setting.

A fine flexible wire fixed to a large screw-head passes alternately under and over the pulleys of the lower and upper series of components, and carries an ink-bottle at its free end. The ink-bottle, fitted with a fine glass point, travels in a geometrical slide, and is suspended to give just sufficient pressure to ensure contact on the paper of the recording barrel.

The recording barrel is fitted with brass pins at equidistant intervals to form the time indications on the paper by perforation. An index for setting is fitted behind the machine at the top of the recording barrel.

The paper, which is continuous and supplied from a reel, passes round two grooved rollers at the back of the main barrel, and is held in position whilst the pins enter the paper, and after receiving the curves is wound round the haul-off drum. The haul-off drum rests on toothed driving-wheels, and by friction turns and slips to accommodate itself at a proper tension to receive the recorded paper. Motion is given to the whole system of wheelwork through the horizontal centre main shaft from a system of clockwork driving-gear at the bottom of the machine, the whole being driven by a weight calculated at about 4 cwt., and controlled by a fan. A warning bell sounds when the weight is nearly run down. The length of the barrel round which the cord is wound is sufficient to give 15,000 turns of the main shaft. This corresponds to about three months' run of curves, and will occupy about one hour to run off. A year's tide-curves for any port will thus occupy about four hours.

The setting of the machine for the prediction of the tide-curves of any port for which the tide-components are known is as follows:—The dials are first turned so that the epoch or time of maximum is exactly under or above the highest or lowest point according as the component is situated on the upper or lower row of components. The cranks are set vertically (the slotted cone of the wheel on the axis having been first released) and the guide-pin thrown out to its proper range to represent the half-amplitude of the component. The proper positions of the hands having been previously determined by calculation for the time of starting, the hands are set and the slotted cones tightened up. The recording barrel is then set to the time and the wheelwork set in motion. The complete setting occupies only a few minutes.

The large dial in the centre is for showing the progress of the record, which can be marked occasionally to facilitate the entry of the dates on the record after its removal from the machine. A few supplementary pins are inserted in the barrel for the better distinction of the hours. Two speeds of travel can be given to the paper, viz., 1 inch and ½ inch per hour. A fixed rod near the recording pen carries ruling pens for the tracing of base lines, such as dock sills, river bars, or mean tide-levels, or if desired can rule the paper throughout its entire depth to represent feet, metres, &c.

To Sir William Thomson my thanks are due for the improved parallel slide and other details, and also to Mr. Légé (the maker of the instrument) for the design of the wheel-gearing.

"The Motion of Two Spheres in a Fluid." By W. M. Hicks, M.A., St. John's College, Cambridge. Communicated by Prof. J. Clerk Maxwell, F.R.S., Professor of Experimental Physics in the University of Cambridge.

The investigation is based on the lemma that the image of a source in an infinite fluid in presence of a sphere consists of a source at the inverse point of the former, and a line sink thence to the centre of the sphere. From this is deduced the image of a doublet whose axis passes through the centre of the sphere, and of one whose axis is perpendicular to this. Thence is found the kinetic energy of motion of two spheres and fluid in which they are immersed, and properties of the motion deduced by Lagrange's eqnations. Amongst other things is considered the action between vibrating spheres.

Physical Society, June 28.—Prof. W. G. Adams in the chair. New Members: Mr. J. F. Moulton, Mr. J. J. Eastwick.—Prof. W. G. Adams exhibited his new measuring polariscope. It consists of three principal parts. The lower section consists of a mirror, a lens, a Nicol's prism, and two other lenses. The upper section consists of lenses and Nicol's prisms arranged in the reverse order. Each lens and Nicol's prism is supported separately by screws, and its position can be altered independently of the others. These two parts form a complete polariscope. Besides these there is a middle piece consisting of two lenses (nearly hemispheres) forming a box to inclose the crystal immersed in oils, their curved surfaces being concentric. The whole middle piece is supported on the tubes of the upper and lower portions, and may be turned about the optical axis of the instrument. The vertical graduated circle carrying the central lenses and crystal may be turned through any angle about its horizontal axis. By means of an arc fastened perpendicularly on the graduated circle with the centre at the centre of curvature of the central lenses, the crystal may be turned about another horizontal axis at right angles to the former, so that the crystal and the central lenses can be turned about each of three axes which are mutually at right angles. By means of a system of toothed wheels in gear with the rims of the central lenses, the crystal and central lenses may be turned separately about the optic axes of the instrument, so as to bring the planes of the optic axes of a biaxial crystal parallel to the plane of the vertical graduated circle.—Sir John Conroy, Bart., read a paper on the distribution of heat in the spectrum. After referring to Dr. J. W. Draper's supposition that all the rays in the spectrum have the same heating effect, and to his statement that owing to the unequal dispersion of the prism for rays of different refrangibility, the method that has been usual for determining the calorific intensity of the various parts of the spectrum is an essentially defective one; the author described a graphical method for eliminating the effect of the unequal dispersion of the prisms, and showed that from MM. Fizeau and Foucault's measurements, and also from those of Lamansky and Prof. Tyndall, that the maximum intensity is about the middle of the visible spectrum, and not at the red end; and, further, that the curves given by various observers as representing the intensity of the heat in different portions of the spectrum, are in reality the "dispersion curves" for the particular prisms employed.—Capt. Abney, R.E., called attention to his published paper on the measurement of the so-called thermo-spectrum, wherein he shows that the distribution of heat in the spectrum is a misnomer, and that what was really measured by Lemansky and Tyndall was the energy absorbed by the lamp-black and the absorption due to the prisms used. He considered that there was no inherent heat in the spectrum. He found that Dr. Draper had not taken into account the amplitude. Prof. Guthrie said that Capt. Abney had expressed what many thought, namely, that heat was radiant energy.—Mr. Grant then described an investigation which he had made into the induction lines round two parallel coils of wire. In the primary coil an intermittent current of electricity from a Leclanché battery flowed; and in the secondary a telephone was connected up to detect the induction sounds. With this apparatus he found that with the coils kept parallel to each other, there were lines, or rather a surface of minimum induction surrounding the primary, and that if the secondary were placed in these lines hardly any induction noise could be detected. A diagram representing a medial section through the coils showed the lines to proceed from the wire of the coils in two curves resembling parabolas—one from each cross-section of the wire outwards.—Dr. Shettle then described his experiments proving the lines of force in a bar-magnet to run spirally round the bar between the equator and poles, the equator being decentred and obliqne across the bar, as shown by diagrams.—Prof. Rowland, of Baltimore, made some observations on the new theory of terrestrial magnetism of Professors Ayrton and Perry. He said the experiments on which the theory was founded had been attributed to Helmholtz, but they were entirely his own, he having gone to Berlin to make them. The new theory had occurred to himself on making these experiments, but he had rejected it because he found that the potential which the earth's surface would require to have would not only cause violent planetary disturbances, but, by mutual repulsion, drive objects off the earth. He had made also an experiment to see if absolute motion of electricity would cause magnetisation, but failed to get any effect from it. Then he resorted to calculation to find the magnetic effect of relative motion by rotation of a charged sphere of perfect magnetic permeability that is more magnetic than iron. He found that when the sphere was uniformly charged and rotating there would be a magnetic field in its interior; but instead of the result of Messrs. Ayrton and Perry, that if the earth were charged to a potential of, he believed, 10^8 volts relatively to interplanetary space, the earth's magnetism would be what it is, he found the necessary charge to be 61×10^{15} volts. In the ordinary atmosphere this potential would produce a spark nine million miles long and discharge across to the moon. If the moon were electrified to the same degree the mutual repulsion would overcome the force of gravity between them. He therefore considered terrestrial magnetism to be still a mystery. He had also thought that the aurora borealis might be explained by supposing the upper regions of the earth's atmosphere electrified. The winds carrying the upper strata towards the poles, electricity would condense there. This hypothesis was still tenable. Prof. Ayrton said that whether or not the new theory of magnetism should be so rejected depended on whether or not Prof. Rowland's calculations, or those of himself and Prof. Perry were wrong. It had been found by Sir William Thomson, from experiments at Arran, that the earth was electrified with respect to the air, and that there is a difference of potential of 30 volts between earth and air for each foot of ascent. This gave 1360×10^{12} centimetre-gramme-second electrostatic units as the potential of the earth. The new theory required the potential to be 1011×10^{11}, supposing the earth to be of solid iron, or about fourteen times more—a wide margin. Prof. Rowland said he had not seen the calculations of Professors Ayrton and Perry yet, but he believed his results to be correct, as he had checked them in various ways.—Mr. Bailley exhibited a modification of Arago's experiment, in which a copper disk is caused to rotate continuously by changing the polarity of four electro-magnets underneath by a revolving commutator.—Mr. Conrad Cooke exhibited a single voltaic element showing the internal current. This is done by forming the glass vessel containing the element into a helical tube between the poles, and hanging a galvanometer needle in the interior of the helix; the internal current deflects the needle.

Geological Society, June 25.—Prof. P. Martin Duncan, F.R.S., vice-president, in the chair.—Edward Garlick was elected a Fellow of the Society.—The following communications were read:—On the evidence that certain species of *Ichthyosaurus* were viviparous, by Prof. H. G. Seeley, F.R.S., F.G.S.—On *Rhamphocephalus prestwichi*, Seeley, an Ornithosaurian from the Stonesfield Slate of Kineton, by Prof. H. G. Seeley, F.R.S.—A contribution to South American geology, by George Attwood, F.G.S. The paper describes a line of country in Spanish Guayana, Venezuela, S.A., commencing from a small town called "the Port of Las Tablas," on the Orinoco River, extending about 150 miles, and consisting of a series of crystalline and altered rocks. Syenite is the first rock met with, and then are found granite, quartz-diorite, hæmatite, and magnetic iron ores, gneiss, slaty rocks, gabbro, and diabase. In the diabase the quartz veins are found to contain large quantities of gold mixed with the vein matter; the alluvial soil in the neighbourhood of the quartz veins also contains gold nuggets and small grains of gold. Although quartz veins are found in great numbers from the river to the interior, none of them have so far

been found to contain gold in any appreciable quantity until the diabase is met with. All the rocks analysed show a higher percentage of silica than is generally found in other localities. Three analyses made from one piece of diabase showing two distinct lines of alteration by weathering (on the original rock), prove that silica is readily dissolved under atmospheric influences, whilst alumina is not. Iron oxides contain more oxygen near the surface than below it. Lime and magnesia are both readily soluble, but lime much more so than magnesia. Soda is more sensitive to weathering than potash. The rocks contain *more combined as well as uncombined* water on their surface than when sheltered from atmospheric influences. The paper was accompanied by an appendix on the microscopical structure of some of the varieties of rocks by Prof. Bonney.—On the so-called Midford Sands, by James Buckman, F.L.S.—On the physical geography of the north-east of England in permian and triassic times, by E. Wilson, F.G.S. In this paper the author seeks to utilise the information he has acquired from the study of the permian and triassic rocks of the above district, towards solving some of the difficult and much debated questions as to their origin. One of the main objects of the paper is to establish the pre-permian origin of the Pennine Chain.—The formation of rock-basins, by J. D. Kendall, C.E., F.G.S.—On the diorites of the Warwickshire coal-field, by S. Allport, F.G.S.—On *Lepidodiscus lebouri*, a new species of *Agelacrinites*, from the carboniferous series of Northumberland, by W. Percy Sladen, F.G.S., F.L.S.—On the ancient river-deposit of the Amazon, by C. Barrington Brown, A.R.S.M., F.G.S. The author described a series of alluvial deposits, varying in thickness from 10 to 160 feet, which have been cut through by the river, and form a series of cliffs, giving rise to striking and characteristic scenery. The succession of beds exposed in these cliffs was illustrated by a number of sections, and it was shown that the strata in question must have been deposited by river action. It was then pointed out that the river is performing two classes of work, namely, cutting away the older sheets of alluvial matter, and depositing the materials derived from them at a much lower level. The interesting phenomena of the cutting of curves by the river, and the abandonment by the river of parts of these curves, giving rise to the formation of lakes, was fully explained; and in conclusion the author showed by a map what vast areas in South America have thus been covered by these alluvial deposits.—The glacial deposits of Cromer, by Clement Reid, F.G.S.—On a disturbance of the chalk at Trowse, near Norwich, by Horace R. Woodward, F.G.S.—The submerged forest of Barnstaple Bay, by Townshend M. Hall, F.G.S.—On a section of boulder clay and gravels at Ballygalley Head, and an inquiry as to the proper classification of the Irish drift, by T. Mellard Reade, C.E., F.G.S.—On the augitic rocks of the Canary Islands, by Prof. Salvador Calderon. Communicated by the President. As the result of a long investigation of the eruptive rocks of the Canaries, and especially of Las Palmas, the author has come to the conclusion that there are two groups of such rocks in those islands, an older one, characterised by the presence of hornblende, and a newer, containing augite. In the latter he finds the essential minerals to be plagioclase, augite, magnetite, olivine, sanidine, and nepheline; and he distinguishes among them the following kinds of rocks, all of which have their characteristic minerals imbedded in a paste of augite and plagioclase:—(1) *Augite-andesite*, with a small quantity of sanidine; (2) *Tephrine*, with no sanidine, but abundance of nepheline; (3) *Basanite*, with some peridote; (4) *Nepheline-basalt*, with abundance of peridote; (5) *Dolerite*, crystalline, characterised by the disappearance of nepheline, the abundance of peridote and porphyritically imbedded plagioclase, and with porphyritically imbedded individuals of augite and olivine; (6) *Felspathic basalt* (like 5), but semicrystalline; and (7) Essentially olivinic modern lavas.—On the Cambrian (Sedgw.) and Silurian beds of the Dee valley, as compared with those of the Lake-district, by J. E. Marr, B.A., F.G.S.—On some superficial deposits in the neighbourhood of Evesham, by the Rev. A. H. Winnington Ingram, M.A., F.G.S.—Descriptions of palæozoic corals from Northern Queensland, with observations on the genus *Stenopora*, by Prof. H. A. Nicholson, M.D., D.Sc., F.G.S., and R. Etheridge, jun., F.G.S. The corals described in this paper were in part collected by the late Mr. Daintree, chiefly from the limestone of the Broken River, regarded as of Devonian age, and in part by Mr. R. L. Jack, from various sources, namely, the Bowen River coal-field, in beds probably of permo-carboniferous age, the Fanning River limestone (Devonian), and the Arthur's Creek limestone (permo-carboniferous). Mr. Daintree's collection also contained corals in the chloritic rock of the Gympsie gold-field. From the Coral Creek, Bowen River coal-field, the authors record *Stenopora ovata*, Lonsd., and *S. jackii*, sp. n.; from the Fanning River limestone, *Heliolites porosus*, Goldf., and *Pachypora meridionalis*, sp. n.; from the Gympsie chloritic rock, *Stenopora?* sp. ind.; from the Broken River limestone, *Favosites gothlandicus*, vars. Lam., *Heliolites porosus*, Goldf., *H. plasmoporoides*, sp. n., *H. Daintreei*, sp. n., *Heliolites*, sp. ind., and *Aræopora australis*, sp. n.; from the Arthur's Creek limestone, Burdekin Down, *Alveolites* (*Pachypora?*), sp., near *A. robustus*, Rom., *Alveolites*, sp. (lobate form), *Aulopora repens*, M.-Edw. and H., *Heliolites porosus*, Goldf., and vars., *Lithostrotion*, sp. ind., *Pachypora meridionalis*, *Trachypora*, sp. ind., and species of *Cannopora* and *Stromatopora*. The genus *Aræopora* is proposed as a new group; the genus *Stenopora* is made the subject of a long discussion; and the geological characters of the deposits from which the fossils are derived are indicated and discussed.

Meteorological Society, June 18.—Mr. C. Greaves, F.G.S., president, in the chair.—Lieut. A. Carpenter, H. Dodd, Capt. D. Galton, F.R.S., S. B. Goslin, A. Gray, Capt. Marshall Hall, W. L. MacGregor, and Rev. W. P. Robinson, D.D., were elected Fellows of the Society.—The following papers were read:—Report on the International Meteorological Congress held at Rome, April, 1879, by Robert H. Scott, F.R.S.—Thermometer exposure: Wall *versus* Stevenson screens, by William Marriott, F.M.S. It being the practice of some observers to expose their thermometers on walls facing north, it seemed a suitable object of inquiry whether instruments so placed gave results comparable with those obtained from thermometers in a Stevenson stand in the open. A pair of meteorological office wall screens were fixed to the brick wall of an outhouse with a northern aspect, so that the screens were in the shade, except in the morning and afternoon of the summer months. The Stevenson screen was on a grass plot 17 feet square, and about 50 feet north of the wall screen. The paper contains the results of the comparison of the maximum and minimum temperatures in the wall screen with those in the Stevenson screen for the twelve months ending March 31, 1879. The figures show that the mean daily maximum temperature on the wall is below that in the open, the monthly differences varying from 0°·0 to − 2°·1, that for the twelve months being − 1°·0. The minimum temperature on the wall was mostly higher than in the Stevenson stand, the differences varying from − 0°·1 to + 1°·3, the mean for the year being + 0°·5. The individual differences, however, are sometimes much greater, the maximum temperature on the wall being considerably lower than that in the stand. For instance, the difference exceeded 4°·0 five times in September, and four times in March, the greatest being 6°·7; these extremes occurred on fine calm days. The minimum temperature on the wall was more than 2°·0 higher than that in the Stevenson stand on five occasions in June, seven in July, and four in September. The mean daily range of temperature on the wall for the twelve months was 1°·4 less than in the stand in the open. The greatest difference was on March 9, when the range on the wall was 8°·5 less than in the stand. These results seem to show that, although the mean temperature may be roughly ascertained from thermometers shaded by a wall with a northern aspect, this method of exposure affords less sensitive indications than those obtained from instruments in a properly exposed Stevenson stand.—On the Hurricane at Mauritius, on March 20th—21st, 1879, by C. Meldrum, LL.D., F.R.S.—On a remarkable disturbance of Barometric Pressure, observed at the Royal Observatory, Greenwich, on May 18th, 1878, by W. Ellis, F.R.A.S.—Meteorology of Mozufferpore, Tirhoot, 1878, by C. N. Pearson, F.M.S.—Meteorological Observations made on the Peak of Teneriffe, by Dr. W. Marcet, F.R.S.—On the temperature of the Atlantic during December, 1877 and 1878, by Capt. H. Toynbee, F.R.A.S.

Entomological Society, July 2.—Sir Jno. Lubbock, Bart., V.P.R.S., president, in the chair.—Mr. Vincent Robert Perkins, of South Belgravia, was elected as an Ordinary Member.—Mr. S. Stevens exhibited living specimens of *Tillus unifasciatus* taken at Norwood.—Mr. McLachlan contributed some further remarks respecting the sculptured pebbles from Lac Léman referred to at the last meeting of the Society.—A number of the perfect insects forwarded by Prof. Forel proved to be *Tinodes lurida*, Curt., a common insect generally on the margins of

lakes and rivers.—Mr. W. L. Distant exhibited a specimen of *Papilio hystaspes*, Feld., taken at sea during a calm thirty miles from Singapore and nine miles from the nearest land.—Mr. W. Cole exhibited a remarkable variety of *Pyrameis cardui*, Linn., taken in Essex.—The Secretary exhibited, on the part of Lord Walsingham, some specimens of a remarkable species of *Tipulidæ* (*Bittacomorpha clavipes*, Fab.) possessing greatly enlarged tarsal joints, captured at Pitt River, California.—Sir Sydney Saunders communicated some additional explanations received from M. Jules Lichtenstein respecting the rearing of the blister beetle, *Cantharis versicatoria*.

Statistical Society, June 30.—Anniversary meeting.—Mr. G. J. Shaw-Lefevre, M.P., in the chair.—The report of the council, the financial statements of the treasurer, and the report of the auditors having been read, the chairman, in moving the adoption of the documents referred to, observed that the Fellows of the Society now numbered 746, and that the increase during the past year over the previous years, and as compared with the average of the last decade (509), indicated the steady progress of the Society. This was confirmed again by the increasing receipts from the sale of the Society's *Journal*. He congratulated the meeting on the satisfactory progress of the Society, financially and otherwise, during the past year. Thomas Brassey, M.P., was elected president. The chairman announced the subject selected for the essays in competition for the Howard Medal of 1880 (with 20*l*.), to be "The Oriental Plague, in its Social, Economical, Political, and International Relations; Special Reference being made to the Labours of Howard on the Subject."

Rome

R. Accademia dei Lincei, June 1.—Prof. Blaserna and MM. Casorati and Brioschi read a report on a memoir by M. Ascoli, on the representability of a function of two variants by double trigonometrical series.—Prof. Blaserna and MM. Felici and Betti read a report on a memoir by Prof. Galileo Ferraris on theorems on the distribution of constant electric currents.—Prof. Blaserna presented a memoir by M. Keller on the secular variation of the magnetic declination at Rome.—The following papers were read:—Contributions to etiology, by M. C. Emery.—Locomotion in the air, by M. Cordenous.—The application of photography to topographical operations, by M. Chizzoni.—President Sella spoke on a paper by M. Valle, a crystallographic study of some bodies of the aromatic series, prepared by Prof. Körner.—M. Lanciani made some demonstrations on malaria and on the subterranean roads in Rome and the Roman Campagna.—On the nature of the specific agent which produces fevers by malaria, by Profs. Tommaso-Crudelis and Klebs.—On the thermic and galvanometric laws of electric sparks produced by complete and incomplete discharges of condensers, by Prof. Villari.

Paris

Academy of Sciences, July 7.—M. Daubrée in the chair.—The following papers were read:—Identity of *Bacillus amylobacter* and the butyric vibrion of M. Pasteur, by M. van Tieghem. The amylobacter, at a certain phase of development, produces a transitory reserve of starch, impregnating its protoplasm. That this occurs in solutions of dextrine or sugar, seems to have escaped the notice of M. Prazmowski and M. Pasteur.—On a new polygraph, an inscribing apparatus applicable to physiological and clinical researches, by M. Marey. He describes modifications by which his apparatus is rendered more portable, simple, and faithful in its indications. In his tambours, the elastic membrane is caught between two annular plates of metal; for transmission of sphygmograph movements he uses caoutchouc tubes rendered inextensible, &c.—On the origin of the excito-sudoral nerve-fibres of the face, by MM. Vulpian and Raymond. The cervical cord of the sympathetic probably contains few, if any, excito-sudoral fibres. The fibres in question come either from sympathetic nerve-fibres accompanying the vertebral artery in its ascending course through the transverse apophyses of the cervical vertebræ and (through these fibres) from the upper thoracic ganglion, or from the parts of the sympathetic coming from the rachidian bulb and the protuberance.—On the inundation of the town of Szegedin, in Hungary, by General Morin. A scientific account of the disaster. From data supplied by Prof. Krusper, of Buda-Pesth, it is shown that in less than fifty years, both as the natural effect of alluvia and that of embankment, the level of flood of the Tisza had risen two metres. General Morin points out the advantage of transferring the clayey and muddy deposits of the river from the lower to the upper parts of the valley, so turning marshes into cultivable land, and increasing the slope of the valley. With this view the dykes of the left bank might be gradually suppressed and replaced by submersible oblique dykes, furnishing successive basins for interception of material.—On the mean value of coefficients in the development of a skew or symmetrical determinant of an order infinitely great, and on doubly skew determinants, by Prof. Sylvester.—Application of sulphocarbonate of potassium to phylloxerised vines, by M. Mouillefert. He gives in a table particulars of the treatments effected by the General Society in the spring of this year. The sulphocarbonate is almost universally applicable for French vineyards, and can be used in any weather or any season without danger to the vine.—On the hypergeometric series and the polynomes of Jacobi, by M. Appell.—On the recent eruption of Etna, by M. Fouqué. The new eruption has produced, on the south-south-west, a fissure having only a few small crateriform apertures, and mouths of emission of lava slightly developed; but on the north-north-east side there are ten distinct craters, two of which are enormous (200 m. diameter, and 80 m. depth).—On the same subject, by M. de Saussure. He describes the phenomena in detail.—Evaporation of water under the influence of solar radiation through coloured glasses, by M. Baudrimont. Green and red, in general, favour the evaporation least, while yellow and red favour it most. M. Baudrimont considers there is probably a simple relation between the number and extent of the luminous waves and the number and extent of those which produce heat, in virtue of which they can be simultaneously propagated through a coloured glass and concur in the effect produced.—Thermo-chemical study of alkaline sulphides, by M. Sabatier.—On a new metal discovered by M. Tellef Dahll, by M. Hiortdahl. He has found it in a mineral composed of arseniuret of nickel (*kupfernickel*) and nickel glance at Oterö, a small island near the town of Krages. He calls it *Norvegium*. It is white, somewhat malleable, and hard like copper ($Ng = 145{\cdot}95$).—On commercial trimethylamine, by MM. Duvillier and Buisine. It is not a simple product, as M. Vincent asserts; of trimethylamine there is only 5 to 10 per cent. in it. Dimethylamine dominates, being about 50 per cent. There are also monomethylamine, monopropylamine, and monoisobutylamine, in nearly equal quantities.—The charbon of ordinary onion (*Allium cepa*), a new disease, originating in America, and caused by an Ustilaginea (*Urocystis cepulæ*, Farlow), by M. Cornu.—Contribution to the physiology of local sweats; local action and antagonism of hypodermic injections of pilocarpine and atropine, by M. Straus.

ROMAN ANTIQUITIES

Roman Antiquities at Lydney Park, Gloucestershire. Being a Posthumous Work of the Rev. William Hiley Bathurst, M.A., with Notes by C. W. King, M.A., Fellow of Trinity College, Cambridge. Pp. vii., 127; Plates xxxi., quarto. (London: Longmans, Green, and Co., 1879.)

LYDNEY PARK appears to be the property of the Bathursts, having been purchased by Mr. Benjamin Bathurst in 1723, so the remains found there have been mostly disinterred under the superintendence of different members of the family in successive generations, and then carefully drawn and described by them. "When the Roman constructions in Lydney Park," the editor tells us in the preface, "were first regularly explored, at the beginning of this century, the Right Hon. C. Bathurst, after taking accurate plans and drawings of the several rooms as they successively came to light, composed a detailed description, in two parts, of the Villa and the Temple." The whole appears to have been found too long and too discursive for publication; so the late Mr. Bathurst, whose name appears on the title-page, "prepared, with great care not to omit any really important particulars, a summary of both these manuscript memoirs; and this forms the text of the volume now printed." But in addition to the papers left by the elder Bathurst, "his daughter, Miss Charlotte Bathurst, had drawn up a descriptive catalogue of coins, selected for their special interest or beauty of condition from amongst the immense quantity found in the course of the excavations." This list Mr. King found "upon examination to exhibit such accurate knowledge of numismatics, coupled with such intelligence in the selection of the pieces," that he has published it without any important alteration; and so far as one can learn from the present volume the Bathursts deserve great credit for this enlightened appreciation of the archæological treasure which had fallen to their lot. But the reader must not be left to conclude that the whole of it has passed through their hands, for Mr. Bathurst says that "Major Rooke, who published some account of this camp in the 'Archæologia,' v. 207, in 1777, was frequently at Lydney, and was allowed to dig wherever he was inclined. Others also were in the habit of searching for coins and other antiquities, and taking them away." Then there has been the usual quarrying for building-stone with the usual result of materially damaging the old pavements, which seem to have still further suffered from a search for iron ore in the limestone of which the hill is composed, on which the camp stood.

So much by way of introduction: I shall not attempt to describe the coins, the articles of bronze or iron, and the tesselated pavements, but confine my remarks to the antiquities relating to the god Nodens, which Mr. King rightly considers to exceed largely in curiosity and value anything of the kind yet discovered in this country. The inscriptions on the votive tablets have long been known, and will be found in the seventh volume of the "Corpus Inscriptionum Latinarum," edited by Hübner for the Berlin Academy. One of them consists of a sheet of lead "carelessly scratched with a graver," and reads in plate xx:—

DEVO
NODENTI SILVLANVS
ANILVM PERDEDIT
DEMEDIAM PARTEM
DONAVIT NODENTI
INTER QVIBVS NOMEN
SENICIANI NOLLIS
PETMITTAS (*sic*) SANITA
TEM DONEC PERFERA[T]
VSQVE TEMPLVM NO
DENTIS.

It is thus rendered by Mr. King: "To the god Nodens. Silvianus has lost a Ring: he has made offering (*vowed*) half (*its value*) to Nodens. Amongst all who bear the name of Senecianus, refuse thou to grant health to exist, until he bring back the Ring to the Temple of Nodens." But why *Silulanus* should be made into *Silvianus* I fail to see; for my part I should regard the former as re-echoing the national name of the Silurians; but that is, of course, another matter.

Another of the tablets is of bronze with *pointillé* letters surmounted with the figure of an animal which the editor pronounces to be a wolf and not a dog as had hitherto been supposed; he believes the vow to have been made on the occasion of an escape from a wolf—it reads thus:—

PECTILLVS
VOTVM QVOD
PROMISSIT
DEO NVDENTE
M. DEDIT.

The chief question which this suggests is what the *M* stands for; Hübner suggests *Marti*, *Maximo*, and *Meritò*, but prefers the two former and gives the first place to *Marti;* but Mr. King does not take this last into account, while he decides in favour of Maximo as against Meritò, and on the whole this seems satisfactory and suits the remaining bronze tablet, which reads in letters, formed in the same *pointillé* fashion as those of the previous one, as follows:—

D. M. NODONTI
FL. BLANDINVS
ARMATVRA
V. S. L. M.

Besides these tablets there have been found at Lydney a number of detached letters cut out of a thin plate of bronze for affixing to a surface by means of small nails in order to make an inscription, as in the case of the *Maison Carrée* at Nismes, excepting that the Lydney ones were, as Mr. King thinks, to be fixed to a wooden surface, probably that of the coffer; but what is interesting is that when sorted the letters make NODENTI SACRVM, excepting that one-half of the letter *s* has not yet been found.

But the inscription which presents most difficulty has still to be mentioned: it is worked into the tesselated pavement of the temple and consists of two long lines. "With the aid of the accurate drawing made at the time of its discovery," and by comparing "the imperfect characters with those well preserved," the editor thinks he has improved on previous attempts to decipher the dedication, which he reads as follows, with the abbreviations extended:—D*eo* M*aximo* IT*erum* FLAVIVS

SENILIS PR*aeses* REL*igionis* EX STIPIBVS POSSVIT O*pitu*LANTE VICTORINO INTER*prete* L*a*TINE. Accordingly he translates:—"To the greatest God, for the second time, Flavius Senilis, Head of the Religion, has erected this, from voluntary contributions, the Director of the works being Victorinus, interpreter for the Latin tongue." On the whole the profession of Victorinus is open to some doubt, as several of the letters following INTER are very far gone; however Mr. King strongly maintains that the hitherto accepted reading of INTERAMNATE is impossible. Perhaps a difference of opinion may still be allowed to exist as to the profession of Flavius Senilis also; but it is tolerably evident both from this inscription and the others already mentioned which were found in the same building, that it was the temple of the god Nodens. That the *D. M.* with which the dedication begins stand for *Deo Maximo* is in Mr. King's opinion put beyond doubt by the heading of the votive tablet of Flavius Blandinus. Such a prelude he thinks is designed to mark the god's supremacy, while his name is superfluous in his own temple, every visitor being supposed to recognise him as "the supreme deity of Siluria." He then goes on to produce reasons for supposing the rebuilding of the temple to have taken place in the time of Agricola and in consequence of the encouragement he gave the Britons to engage in works of civilisation. But the fact of the re-erection taking place under the eyes of the Romans will prepare the reader to find this Silurian deity represented in the classical fashion. Mr. King thinks that he was meant for a sea or river god, and that fact is, in his opinion, "placed beyond doubt by the design of the pavement, *dedicated to him*, be it observed, that decorates the floor of the temple." The description he gives of them is as follows (p. 39):—"The centre is formed by two sea-serpents, represented in the usual form given by the Greek painters to the dreaded κῆτος, as it is seen in the Pompeian wall-painting of Perseus and Andromeda. This sea-monster closely resembles the ichthyosaurus of geologists, with its elongated neck and pectoral paddles, or 'flippers,' which are coloured bright red in our mosaic to augment the savageness of its aspect. The field is occupied with figures of fish, evidently salmon, the chief glory of the Severn." We have not yet done with the pavement, for in the part occupied by the dedicatory inscription, but not quite in the centre, seemingly not to cut up the names, as Mr. King thinks, there is what he describes as "a circular opening, nine inches in diameter, surrounded by a broad red band, again inclosed in two others of blue. That some high mystery was involved in the setting of this unsightly object in so conspicuous a position cannot admit of any doubt." He comes to the conclusion that this funnel was meant to receive libations poured to the god, and that they were drunk up by the dry soil beneath. He further compares this opening in the pavement "to the well of salt water, that famous memorial of the former presence of Poseidon, in the Acropolis of Athens."

In addition to the foregoing inscriptions there has been found there what is described by the editor as "a bronze plaque, clearly intended for personal decoration; the most obvious purpose to which it can"—he thinks—"be assigned, being that of the frontlet of the head-dress worn either by the idol itself or by the officiating priest, after the manner of the large ornamented disks of thin gold so frequently turned up in Ireland." The following is his description of this ornament:—

"In the centre rises a youthful deity . . . . he is crowned with rays like Phœbus (or more probably 'his bonnet sedge,' like Camus), carries a sceptre, and is borne over the waters in a car drawn by four sea-horses, like the Roman Neptune. On each side floats in the air a winged Genius, clearly typifying the Winds, one holding forth in his right the leaf-shaped fan commonly seen in the hands of Roman ladies; the other Zephyr similarly waves a handkerchief; both grasp in the left hand the end of the shawl or *chlamys*, thrown loosely over each arm. Rude as is the engraving, there is a lightness and freedom in the drawing of these figures much to be admired, and expressing with great truth the airy nature of the beings it attempts to embody. Each end of the composition is filled up with a reclining Triton; the one brandishing two paddles of the very shape still employed by those that navigate the primitive British bark, the coracle; the other, an anchor, and his proper attribute, the shell-trumpet, the *cava buccina*, assigned to him by Ovid."

There remains another piece of ornamentation, which Mr. King regards as a fragment of the foregoing; but I must give his own words:—

"On the smaller fragment, evidently part of the same decoration, Triton is yet more distinctly represented; he is here winding a blast on his conch to call the winds to do him service, whilst he wields the anchor for sceptre; on the other side sits the votary of Nodens, the Silurian fisherman, enveloped in the hooded frieze mantle worn to this day by his brethren of Naples, and who, by the favour of the god, has just hooked a magnificent salmon."

Mr. King is somewhat unlucky when he comes to touch on questions of Celtic philology, as will be seen from the following extract:—

"Dr. McCaul quotes from a letter from Meyrick to Lysons that 'Deus Nodens seems to be Romanised British, which correctly written in the original language would be Deus Noddyns, the "God of the abyss," or it may be "God the preserver," from the verb *noddi*, to preserve; both words being derived from *nawdd*, which signifies protection.' Prof. Jarrett, a profound Celtic scholar, to whom I applied for a translation of 'Deus Noddyns' without mentioning Meyrick's explanation, at once rendered it as 'God of the deeps,' a sense that every circumstance confirms."

What Meyrick may have said to Lysons on Celtic philology had best be forgotten, and with all respect to a Celtic scholar with whose name I do not happen to be acquainted, it will be at once admitted by all those who know Welsh, that *Noddyns* is gibberish; nay, I might go so far as to say that it could not be made to fit into the vocabulary of any Celtic language past or present. The word which in all probability suggested it to Meyrick was *anoddyn* or *anoddyfn*, "abyss," with which *Nodens*, however, could not, according to any known rules of Welsh phonology, be connected. This wretched bit of philology does not, I am glad to say, vitiate the rest of the editor's reasoning, which seems to me so good that I should like to put him on another tack. In a lecture not yet published, but delivered before the present volume was published, I ventured to equate the name of the god with that of another, which I thought I detected in an Irish proper name: I allude to Mogh Nuadhad (in an older orthography Mog Nuadat), the name of a Munster prince

well known in Irish legend. It means the slave or servant of Nuadha, and belongs to a group of Irish proper names which I take to be of a Non-Aryan origin, and to mark the præ-Celtic race of Ireland. Another of the same kind was Mogh Néid, the slave or servant of Néid; for the Ancient Irish had a god of war called Néid or Nét.

This kind of nomenclature, I need hardly say, is well known on Semitic ground: take, for instance, the biblical *Abdiel*, "servant of God," or the inscriptional *Abdastartus*, "servant of Astarte." On the other hand the Aryans gave the preference to compounds such as the Sanskrit Deva-datta, Greek Θεό-δοτος, or the Welsh *Cad-wal*, Irish *Cath-al*, Old German Hatho-wulf, or the wolf of war. To return to Lydney, the name *Nodens*, genitive *Nodentis* is precisely what would make in Irish, according to the phonological laws of that language, a nominative *Nuadha*, genitive *Nuadhat*, that is on the supposition that the first syllable of the god's name was long, *Nōdens* or *Nūdens;* further, corresponding to an Irish nominative *Nuadha*, the Welsh form should be *Nudd*, with *ū* pronounced nearly like German *ü*, and *dd* like *th* in the English word *this;* and Nudd occurs in Welsh both in prose and verse, namely, in connection with *Edern son of Nudd* and *Gwyn son of Nudd*, where it probably meant a god-ancestor rather than the father; compare Bran son of Llyr, that is, Bran son of the Sea. Even the hesitation in spelling between *Nodens* and *Nudens* fits exactly into Welsh phonology, which makes both the ō and the ū of the language in its early period into ū in its later stages; from the Lydney inscriptions this would seem to have been nearly accomplished in the first century.

It is unfortunate that Welsh literature gives us no information as to the attributes of Nudd; the case is much the same with Nuadha in Irish literature, but it is right to say that the latter makes Nuadha to be a king of the Tuatha Dé Danann, that is to say, king of the most mythical race in Irish legend, and the following passage in O'Curry's Lectures on the Manners and Customs of the Ancient Irish (iii. 156) is to the point, though he gives no reference to the original, which he had in view in it:—"The river Boyne, from the clearness of its waters, was poetically called *Righ Mná Nuadhat;* that is, the wrist or forearm of *Nuadhat's* wife. This lady was one of the *Tuatha Dé Danann;* and the poetical allusion to her arm originated from her keeping it constantly covered with rings or bracelets of gold to bestow upon poets and musicians." I am inclined to think that the term *Righ Mná Nuadhat* had a much deeper meaning, and that it is, in fact, a relic of Irish mythology. For there is good ground for believing that the Boyne was personified and probably worshipped; I conclude this from the meaning of its name, which was in Old Irish *Bóind*, genitive *Bóindeo*, and in Ptolemy's Geography Βουουίνδα, *i.e.*, *Buwinda*, which has been equated and, no doubt, correctly with the Sanskrit adjective *govinda*, which, according to the Petersburg Dictionary, means "acquiring or winning cows or herds," and occurs as an epithet to Brhaspati, Krsh*n*a, and Vishnu. In Cormac's Glossary we learn that the Boyne had another name, Bergna or Bregna, which also appears to have been personal. In Britain, the Dee, for example, was undoubtedly regarded as a divine stream, and probably also Ptolemy's Belisama wrongly identified in my Lectures on Welsh Philology with the Dee. If, then, the Boyne was such another river divinity, nothing could be more natural than for the muse of mythology, if I may use the term, to marry her to Nodens, god of the sea, if it is right, as it seems to be, to describe him as such.

Mr. King touches on several minor points of great interest to Celtic philologists, as, for instance, when he says of Senilis, "that his uncommon *cognomen* is probably a translation of his British name, *Hen*, the Old;" but it is hardly necessary to speak here of a translation, as at the date of the dedication *hen* was *sen* in all Celtic languages, and the Welsh change of initial *s* into *h* did not set in for centuries afterwards. With *Senilis* may be compared or contrasted the Senilus of the post-Roman inscription of St. Just in Cornwall, see p. 406 of the Lectures on Welsh Philology, and also the "Grammatica Celtica," p. 769, where an Irish name is mentioned as written *Sinill*, with which may be compared the *Senyllt* of later Welsh: more than one of these forms seem to postulate a Latin Senilius. Hübner has other instances of *Senilis* besides the one from Lydney. Quite distinct from the fortune of initial *s* was that of vowel-flanked *s*, as it has disappeared without a trace both in Welsh and Irish, and that probably at a very early date: possibly before they had differentiated themselves into distinct languages. The Lydney inscriptions seem to me to give strong indirect evidence to the effect that it had in this country disappeared before the first century; for the best explanation of the doubling of the *s* in POSSVIT and PROMISSIT is to suppose the inscriber to have been a Celt, in whose language, as in Welsh and Irish, a soft *s* or single *s* between vowels was unknown; his mistake could be copiously paralleled by the way Welshmen of the present day deal with English *s* and *z*. I suspect also that the Celtic word for god, of the same origin and derivation as the Latin *divus* and beginning, as it must have in early Welsh, with the syllable *dēv*, had not a little to do with the spelling DEVO in the tablet of Silulanus.

I cannot end this somewhat lengthy notice without heartily thanking Mr. King and the Bathursts for a volume so full of interest and so well got up.

JOHN RHŶS

THE RIGHTS OF AN ANIMAL

The Rights of an Animal; a New Essay in Ethics. By Edward Byron Nicholson, M.A., Principal Librarian and Superintendent of the London Institution. (London: C. Kegan Paul and Co., 1879.)

THIS is a little book—too little to be satisfactory. Its object is to argue that "*animals have the same abstract rights of life and personal liberty with man.*" The ambiguity which attaches to the word "same" in this opening statement of the "principle" to be proved casts its shadow over all the remaining sixty pages of which the essay consists. That animals have not in all respects *identical* "rights of life and liberty with man" is too obvious a truth for even Mr. Nicholson to combat. He neither objects to the slaughtering of animals for food nor to the working of animals for purposes useful to man. Yet if the rights of animals were, strictly speaking, "the same" as those of man, the former act

would be one of murder, and the latter one of unjustifiable slavery. It is clear, therefore, that for the purpose of lucid statement we ought to be supplied with some definition of the sense in which the author supposes the rights of animals to be comparable with those of man. And it is because this definition is nowhere supplied that we deem the work unsatisfactory. That animals, as sentient creatures, have *some* rights—*i.e.*, that man may not kill or torture them needlessly without incurring *some* moral blame—no one nowadays would undertake to dispute.[1] It therefore seems useless to fill a number of pages with a number of truisms on the theme that animals have some rights in common with man. From the writer of "a new essay in ethics" we expected to find a statement of the principles by which the rights of animals ought to be defined—in what they resemble and in what they differ from the rights of man, and why. But instead of this we find only the statement of a fact which it does not require "a new essay in ethics" to reveal, viz., that the immorality of subjecting animals to needless death or torture cannot be justified on the ground of any such irrelevant or untrue arguments as that animals are irrational, not immortal, or non-sentient. Such being the whole scope of the work, it seems to us to be about a century too late in appearing.

At the present time, when the ethics of vivisection and kindred questions are being so warmly discussed, there is a good opportunity for a competent essayist to write an interesting, if not valuable treatise, on the basis, the nature, and the extent of animal rights, as well as the ways and degrees in which these rights ought to be respected by man. The latter subject is lightly touched by Mr. Nicholson in his concluding chapter, entitled "Limitations in Practice." His view appears to be that man has no moral justification in taking the life of any animal, which is not either directly "harmful" to himself or in competition with him in "the struggle for food." Therefore Mr. Nicholson considers it immoral to eat shrimps and lobsters, seeing that they neither "hamper man's comfort nor eat up his food." Criticism here is sufficiently easy. Among animals themselves the only right is might, and therefore if a lobster could argue with a philosopher it is difficult to see on what grounds he could convince the superior animal that the latter has less right to eat him than has his brother lobster. If the lobster were to urge that the philosopher is not merely an animal but a moral animal, the philosopher might answer that he cannot see any moral justification of the lobster's view that the right of an edible animal to live is superior to the right of an eating animal to kill. And if the lobster were unfortunate enough to quote Mr. Nicholson as an authority to prove that man has a moral right to kill only "hurtful" animals, it would be competent for the philosopher to reply that if man has a moral right to promote his own happiness by killing animals which cause him harm or annoyance, it is impossible to see why he should not have a similar right to promote his own happiness by killing all animals that serve him for food.

[1] Dr. Whewell is probably the last of competent writers who has done so in the past or is likely to do so in the future. It is remarkable, by the way, that Mr. Nicholson does not quote the passage in which Dr. Whewell sneers at Bentham for maintaining the rights of animals as sentient creatures, for this passage, especially as answered by Mill, would have gone further to argue the existence of obtuseness upon this subject than does any other fact which is mentioned by Mr. Nicholson.

Lastly, if the lobster were to argue that his enemy might secure a doubly beneficial end by limiting his diet only to such animals as are noxious, the philosopher would be compelled to observe that he happened to prefer lobster salad and roast lamb to boiled snakes and rat-pie.

The same inconsistency of principle is displayed where Mr. Nicholson treats of vivisection. He says "much against my feelings I do see a warrant for vivisection in the case of harmful animals and animals which are man's rivals for food." But if man has a moral right to slay a harmful animal *in order to better his own condition*, he must surely have a similar right to slay a harmless animal, *if by so doing he can secure a similar end.* And of course it is the opinion of all sufficiently informed persons that vivisection has been of more service in bettering the condition of humanity than has the destruction, say, of wolves, bears, and tigers, wherever these animals have been destroyed.

OUR BOOK SHELF

Proceedings of the Aberdeenshire Agricultural Association, 1878.

We have already noticed the earlier field experiments made by this Association. The most prominent fact which they believe they have established is the efficacy of mineral phosphates, when in fine powder, as a manure for turnips. Such phosphates have always been treated with sulphuric acid, and converted into superphosphate before being employed as manure; to employ them in fine powder without this previous treatment would of course be more economical, if they are in this state sufficiently effective.

It would be easy to criticise the experiments on which the above conclusion is based; we might especially point out the very different results which the same manure has yielded on different plots of the same land. The manure has also apparently been incorporated with the soil in a far more perfect manner than would be possible in agricultural practice, and the solvent action of the soil has thus been greatly aided. We must leave therefore any conclusion as to the feasibility of employing finely-powdered apatite or coprolite as a manure until repeated trials have been made on a large scale. There are, however, a few facts in the chemistry of the question to which we should like to call attention.

If we were asked to describe a soil which should exercise the greatest solvent action on phosphate of calcium, we should certainly name one containing much humic matter, and little or no carbonate of calcium. The humic matter, and the carbonic acid produced from it, would act as a tolerably powerful solvent for the phosphate, if carbonate of calcium were not present to neutralise their efficacy. Now the granite soils of Aberdeen belong precisely to the class of soil just described; if, therefore, it should be finally proved that finely-powdered mineral phosphates are almost as effective as superphosphate on land of this character, it will by no means follow that the same result will be obtained if the phosphate is applied to other soils, and especially to those derived from limestone rocks.

As to the effect of nitrogenous manures on the turnip crop, the conclusion first arrived at by the Association has been somewhat modified. In the previous report it was stated that the only effect of nitrogenous manure was to increase the amount of water in the crop; this extraordinary conclusion has not been confirmed by the succeeding experiments. As the turnip crop contains a large amount of nitrogen as a necessary constituent, it is clearly ridiculous to speak of nitrogenous manures as

only capable of increasing the proportion of water in the crop; if nitrogenous manures are found in any case to be of little value, it is not because the plant does not require nitrogen, but simply because the soil supplies an abundance without the aid of manure. Concerning the richness of the experimental soils in nitrogen nothing is said. Mr. Jamieson, the chemist of the Association, has, however, stated in another publication that the Aberdeenshire soils usually contain 0·4 per cent. of nitrogen. If this is the case, there is little reason to wonder at the small effect of nitrogenous manures. The amount of nitrogen just named is far in excess of that usually found in arable soils, and about equal to what we should expect to find in the soil of a well-manured kitchen garden.

The percentage of water in a plant is always increased by anything which increases its luxuriance: a big turnip is sure to contain a greater proportion of water than a little one. If, therefore, we are to condemn manures simply because they increase the percentage of water, we may as well stop manuring altogether. It is quite right, however, that the percentage of water in the produce should be taken into account in comparing the effect of different manures, as it is clear that only the dry matter of the crop can have any feeding value.

The experiments, as before, exhibit a vast amount of painstaking work, and cannot fail, if continued in the same spirit, to be of service to the farmers of Aberdeen.

A History of British Freshwater Fishes. By the Rev. W. Houghton, M.A., F.L.S., Rector of Preston-on-the-Weald Moors, Wellington, Shropshire. Two volumes, extra large 4to. (Copies to be obtained from the author at the above address.)

THE most complete monograph on this branch of natural history which has yet appeared, several species of *Salmonidæ* being illustrated for the first time. The coloured figures and the engraved lake and river scenes, which head each chapter, are admirable works of art. The book is exquisitely got up, and is well suited to the drawing-room table. At the same time, it is of real scientific value to the amateur ichthyologist, the descriptions and plates rendering the species of easy identification. The preliminary chapters on the classification and anatomy of fishes are carefully written and well illustrated. The work will add to Mr. Houghton's reputation as an intelligent and accomplished naturalist. C. C.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

The Price of the "Memoirs of the Geological Survey"

THE publication of Mr. Skertchley's "Manufacture of Gun Flints," in the Memoirs of the Geological Survey, seems to be a good opportunity for again bringing under notice the absurd price charged for some of the Survey volumes. In NATURE, vol. xviii. p. 562, Prof. Boyd Dawkins drew attention to this subject, and urged the necessity of issuing the "Memoirs" at a reasonable price; but this last publication shows that the Stationery Office does not intend to mend its ways, but will still try and put the information it issues as far as possible out of the reach of the public. The fact I should like to draw attention to as regards the price of the "Memoirs" is the absurdity of the amount charged for some of the volumes, as proved by others issued by the Survey; and a glance at the facts seems to show that the prices are fixed without any regard to the size or quality of the book. Mr. Skertchley's pamphlet consists of 80 pp. and 71 figs., and this, in a paper wrapper, is priced 17*s.* 6*d.*! Now, take Prof. Jadd's "Geology of Rutland," this contains 320 pp. (or exactly four times as many as Mr. Skertchley's) 11 plates and 19 woodcuts, and the price of this, in cloth, is 12*s.* 6*d.*, or 5*s.* less than the one of 80 pp. Another example is Mr. De Rance's Memoir on the "Superficial Geology of the Coasts of South-west Lancashire," which consists of 139 pp., and 20 woodcuts, and for which we have to pay 17*s.*; compare with this Mr. Woodward's "East Somerset and Bristol Coalfield," containing 271 pp., 9 plates, and 23 woodcuts, which is only one shilling more than the last-named, and is issued in cloth. But perhaps the most curious two to take together are Mr. Skertchley's volume on the "Fenland," and Prof. Green's "Report on the Yorkshire Coalfield." The former of these contains 335 pp., 24 plates, and 36 woodcuts, and is published at 2*l.*, the latter has 823 pp., 26 plates, and 125 woodcuts, and yet the price is only 2*l.* 2*s.* It is certainly hard to understand why we should be charged 2*l.* for Mr. Skertchley's volume, if one the size of Prof. Green's can be produced for 2*l.* 2*s.* One would imagine that books issued with the public money would be sold as cheaply as possible; and it is to be hoped that some friend to Science in Parliament will ask a question of the Government, and see if it is absolutely necessary that these Memoirs should be published at such famine prices.

Oxford JAS. B. BAILEY

The Sea-Serpent

IN NATURE, vol. xix. p. 286, I observed some remarks respecting sea-serpents, and especially noted one passage which stated that "The age of incredulity is past, and naturalists are now prepared to admit that several distinct kinds of oceanic monsters probably exist."

I was pleased to read this statement, as I have for many years been convinced that some of the accounts published from time to time in the newspapers are accurate descriptions of what has actually been witnessed, but I little expected that I should so soon be able to forward to you a description of one of these creatures, as given by an eye-witness, of whose accuracy there can be no question, and whose observations were made when very close to the animal.

Busselton is a little seaport about 150 miles south of Fremantle, on the west coast of Australia, situated on the shore of Geographe Bay, which is sheltered by Cape Naturaliste; the northern point of that singular projection on the south-west corner of Australia.

During the greater part of the year the water of Geographe Bay is as smooth as a lake, though it is a portion of that vast Indian Ocean which extends unbrokenly to the African coast. The beach is of smooth white sand, so hard at the water's edge that it is frequently used as a road for riding or driving from Busselton to Lockville; the latter place, a few miles to the north, is the station of the Ballarat Timber Company, containing their steam saw-mills, the termination of their railway, and the jetty from which large quantities of that imperishable and valuable timber called jarrah is exported to be used as piles, railway sleepers, &c.

Last month I heard a report that the sea-serpent had been seen near Busselton, and that the resident clergyman had been one of the spectators. Having the pleasure of personal acquaintance with that gentleman, I wrote to him on the subject, and received from him such an interesting account, that I applied to him for permission to communicate the facts to your paper, and verify them by publishing his name. It is fortunate that the principal eye-witness was an educated gentleman, who has for twenty-seven years been a Colonial chaplain in this colony, and whose description of what he saw is clear, simple, and free from exaggeration.

I copy from the letters of the Rev. H. W. Brown the following extracts:—

"On Sunday, March 30, I left Lockville just as the sun was setting, on my way home by the beach.

"The afternoon had been oppressively hot, not a breath of wind, and the sea was as smooth as a glass. I met C. M'Guire and his wife walking towards Lockville.

"Soon afterwards, when abreast of the track to Richardson's, I noticed ahead of me what looked like a black log of wood in the water a stone's throw from the shore, nearly end-on to me, and apparently more buoyant at that end; getting nearer, I noticed that it was *drifting* apparently towards Lockville, and soon discovered that it was moving, leaving behind it a very long, narrow ridge on the smooth water. I then turned my horse's head, and, at a walking pace, kept just abreast of it, un-

noticed apparently, till I had gained sufficiently on M'Guire to make him hear. I then coo-eed *once;* he turned and came back to meet me; but at the sound of my coo-ee the fish started off seawards out of sight (under water), and doubled again in-shore, but so rapidly as to leave both outward and inward "ridge" on the water distinctly visible at once, like a wide V with quite a sharp corner. It gave me the idea of two fishes, the one darting outwards, the other crossing its track inward at the same moment.

"Not knowing where it might show up next, but satisfied that it had come in-shore again, I tried by pointing seaward to direct M'Guire's attention that way.

"Just as I met him the fish again came to the surface, showing gradually more and more of his length, till, when he was almost at rest, and all apparently was in view, I estimated the length to be 60 feet, straight and taper, like a long spar, with the butt-end, his head and shoulders, showing well above the surface.

"I can only describe the head as like the end of a log, bluff, about two feet diameter; on the back we noticed, showing very distinctly above water, several square-topped fins."

I here make an exact tracing from Mr. Brown's letter of his sketch:—

"It was now getting rather too dark to see details distinctly. The fish proceeded towards Lockville, and I turned homeward. M'Guire said he would go on to Lockville jetty and look out for him there.

"Whether he saw him again I know not, but M'Mullan, the fisherman, told me next morning that he had seen it about fifty yards from that jetty, and it looked to him about twenty feet long. So it did to me while in motion; only when at rest for a moment did its whole length show up sufficiently. What its propelling power was I cannot say from observation; I saw no lateral fins and no fish-tail.

"When it started away at the sound of my voice, it was with the rapid movement of a pike or sword-fish, and yet the thick, bluff head had but little resemblance to a snake's.

"There was an unusual abundance of fish close in-shore the same afternoon, yet when I saw the stranger there were certainly no fish of which it could be in pursuit."

Since the year 1848, when the captain and officers of a British man-of-war gave evidence that they passed within 100 yards of a snake which they estimated to be 60 feet in length above water with probably 40 feet beneath, I do not know of any more clear account than the above. Many independent accounts of the existence of marine monsters have been placed on record, and it seems mere folly to treat these repeated reports with ridicule.

I trust that your readers will no longer doubt that "the age of incredulity" is past.

Colonial Surgeon

Fremantle, W. Australia, May 19

Mechanical Difficulty in Growth of Plants and Animals

IN reading reports and discussions on natural science, to which I am, from great pressure of other occupation and studies, only able to give a cursory attention, I cannot find any allusion to the *mechanical* means by which the growth of organised creatures is produced, especially when that growth takes place in opposition to the direction of gravitation. The explanation at which I have arrived of this phenomenon may probably be known to physiologists, and may have been acknowledged or disproved; any way I think the subject might be fairly discussed in a popular journal such as yours.

The growth of the roots of a plant and of drooping branches not being in opposition to the attraction of the earth, presents only the difficulties which arise from vital action, but the increase of a plant in height requires also explanation as to how the work is done of lifting vegetable matter higher and higher; capillary attraction can bring fluid to the summit of a tube such as the stem of a plant, but the fluid cannot overflow at the top, since in that case the matter of the tube would lift the fluid above itself; but when a tube is full of fluid, additional heat expanding this fluid would cause it to overflow at the top of the tube. As the sap contains solids in solution, from this the fluid could deposit an additional length of tubing, in which again an additional length of the column of fluid could be absorbed, so the heat of each day would build up a higher vertical tube, and capillary attraction would account for the cooler fluids produced at night or rising from the root filling the vessels to their extremities. It seems to me, therefore, that the work done in lifting vegetable matter to the apex of a plant is due to the increase of heat in the daytime; that then the watery particles are evaporated, and the solid left deposited in the form of cylindrical vessels of small bore. In animals the prostrate posture of rest allows of growth without the difficulty of resisting gravitation; it is well known that deficiency of sleep (perhaps more accurately of rest) stunts the growth of animals, and that illnesses which keep children in bed during their years of growth almost always cause a rapid increase of stature; surely this arises from the newly-formed tissues having no gravitation to overcome, and therefore developing rapidly. Probably if a child were taught to take rest in a vertical position, it would not grow tall, but develop in breadth.

The work done in increasing the stature of plants every year must be enormous; in one summer thousands of tons of vegetable tissue must be raised through heights varying from a few inches in an oak, to twenty or thirty feet in a hopbine, and much more in a lliano, or tropical creeper. I presume in winter the cold constricts the vessels, and so prevents sap from rising, hence there is no growth at that season.

Taunton College School H. P. KNAPTON

Chemical Notation

IN Mr. Pattison Muir's very interesting article on thermo-chemical investigation (NATURE, vol. xx. p. 8, I find the following:—

"That system of notation which is now employed in chemistry, although of the greatest value, is nevertheless far from being perfect; it fails to tell anything concerning the changes in forms of energy involved in those changes of distribution of mass (matter?) which it formulates."

The author does not, however, propose any addition to the usual notation for the purpose of indicating the transformations of energy which take place in chemical transformations, yet this may be done very simply.

The symbol for water is $HO\frac{1}{2}$. This states with perfect clearness the fact that a molecule of water has been formed by the combination of a molecule of hydrogen with a half molecule of oxygen, but it leaves out of account the important fact that in the act of their combination 34462 heat-units have been given out. If we call a heat-unit θ, the symbol for water will then be $HO\frac{1}{2}—34462\ \theta$; the negative sign indicating that the heat has been *parted with*. I propose to call such compounds thermo-negative. Products of perfect combustion, such as water and carbonic acid, are necessarily thermo-negative.

There are thermo-positive compounds, of which protoxide of nitrogen is one of the best understood. According to Fabre and Silbermann, 1154 heat-units are given out in the separation from protoxide of nitrogen of one gramme of oxygen. It is obvious that this heat must have been *taken up* in the formation of the protoxide. Multiplying 1154 by 8 for the equivalent of oxygen, we get 9232 as the thermal equivalent of the protoxide, and we write its symbol $NO + 9232\ \theta$.

Peroxide of hydrogen is usually written HO, but this, from the point of view of chemical structure, is altogether wrong. Fabre and Silbermann "estimate the heat evolved during the liberation of one gramme of oxygen from peroxide of hydrogen at 1363 heat-units. Multiplying by 8 as before, we have 10904 as its thermal equivalent, regarding it as a thermo-positive oxide of water, and we write its symbol

$$(HO\tfrac{1}{2} - 34462\ \theta) + O\tfrac{1}{2} + 10904\ \theta.$$

JOSEPH JOHN MURPHY

Old Forge, Dunmurry, Co. Antrim, July 8

Local Colour-Variation in Lizards

MR. HENRY HILLYER GIGLIOLI remarks (NATURE, vol. xix. p. 97) that the common lizard (*Podarcis muralis*) constantly presents dark varieties on islets adjoining small islands. A similar case has come under my observation in the herpetological fauna of this country. *Ameiva* (cnemidophorus) *vulgaris*, Licht., is very common all over Venezuela, and though it varies considerably in colour, it is, on the mainland, never black, as on the small islands of Los Roques and Orchila, which lie a short distance off our Caribbean coast. Both islands have rather extensive sandy beaches, covered with a very scanty vegetation, so that, *mutatis mutandis*, they are, in the very words Mr. Giglioli uses when speaking of Filfla, painfully white in the glaring

tropical sun, the black lizards being therefore most conspicuous. Prof. Peters, of Berlin, to whom some years ago I sent specimens of these reptiles, called them in one of his letters *Cnemidophorus nigricolor*, but as I am not aware of his having published this name, I believe he got soon convinced of its true character as a melanotic variety. I may be allowed to add that I have mentioned this case already in my "Estudios sobre la Flora y Fauna de Venezuela" (Caracas, 1877), pp. 280, 281, when I also pointed out the difficulty of its explanation by the "struggle for existence" theory. Caracas, May 15

Intellect in Brutes

1. THE following case was witnessed by my friend Dr. Rafael Villavicencio, of Caracas, during his stay last year in the town of Ponce, in the Island of Portorico:—

The little river in the neighbourhood of the town had risen, in consequence of heavy rains, and ran with rather considerable swiftness. In a certain place it is crossed by a road, where it was forded by a countryman sitting on his mule cart. His dog swam after him, but was taken down by the current and carried back to the bank. Then, after a moment's hesitation, the animal ran some distance up the bank, jumped into the water, and managed to reach the other side just where the road emerged from the river, acting thus precisely as a boatman might have done in similar circumstances.

2. To my friend Dr. Velasquez Level, a respectable physician of this city, and for several years a resident of the Island of Margarita, I am indebted for the following touching instance of the sagacity of a bitch. Her owner, for some reason or other, had destroyed all the female puppies in two successive litters. On her having brought forth a third one it was found that there were but three male puppies. The bitch, however, was observed to leave her whelps occasionally, and to return some time after. Being followed, she was discovered suckling three female puppies, which she had hidden under some brushwood, undoubtedly with the intention of saving them from the master's cruel hands. This case happened in a small place, called Juan Griego, on the northern side of the island. A. ERNST

Caracas, May 15

Intellect in Brutes—a Cat and a Mirror

MANY years ago at Carne farmhouse, where relatives of mine were then living, the household cat was observed to enter a bedroom in course of being spring-cleaned.

The looking-glass being on the floor the cat on entering was confronted with its own reflection and naturally concluded that he saw before him a real intruder on his domain.

Hostile demonstrations were the result, followed by a rush to the mirror and then meeting an obstacle to his vengeance, a fruitless cut round to the rear. This manœuvre was more than once repeated with of course equal lack of success. Finally the cat was seen to deliberately walk up to the looking-glass keeping its eyes on the image, and then when near enough to the edge, to feel carefully with one paw behind, for the supposed intruder, whilst with its head twisted round to the front it assured itself of the persistence of the reflection.

The result of this experiment fully satisfied the cat that he had been the victim of delusion and never after would he condescend to notice mere reflections, though the trap was more than once laid for him. THOS. B. GROVES

Butterfly Swarms

EVEN your varied correspondence from all parts of the world has rarely furnished us with such a wonderfully complete and interesting personal observation as that of Mr. Sydney B. J. Skertchly (NATURE, vol. xx. p. 266) on the West African breeding-grounds of *Vanessa cardui*, and the almost mechanical impulse and simultaneity with which such a swarm as that which he describes free themselves from the pupa-case and set forth on their migration. Can any one throw a similar light on the periodicity of *Colias edusa?* *V. cardui* is a more constant insect in this neighbourhood than any other with which I am acquainted; but the numbers in June of this year were quite unusual. Also we remarked that they were very high-coloured and vigorous, unlike the ordinary washed-out hybernated specimens of early summer. As one of your correspondents has remarked of his neighbourhood, so here *C. edusa* swarmed in 1877. It was the prevailing insect. In 1878 we had hardly a solitary example. The so-called *C. helice*—the pale variety of *C. edusa*—was frequent in 1877. I saw none of *C. hyale;* indeed, have never seen that insect here. HENRY CECIL

Bregner, Bournemouth

REPORT OF AN UNUSUAL PHENOMENON OBSERVED AT SEA

THE following Report to the Admiralty has been communicated to us for publication by Capt. Evans, C.B., F.R.S., the Hydrographer to the Navy:—

H.M.S. *Vulture*, Bahrein, May 17, 1879

SIR,—I have the honour to inform you that, at about 9.40 P.M. on May 15, when in lat. 26° 26′ N. and long. 53° 11′ E., a clear, unclouded, starlight night, Arcturus being within some 7° of zenith, and Venus about to set; wind north-west, force 3, sea smooth, with slight swell from the same direction; ship on starboard tack, heading west-south-west and going three knots, an unusual phenomenon was seen from the vessel.

I noticed luminous waves or pulsations in the water, moving at great speed and passing under the ship from the south-south-west. On looking towards the east, the appearance was that of a revolving wheel with centre on that bearing, and whose spokes were illuminated, and looking towards the west a similar wheel appeared to be revolving, but in the opposite direction. I then went to the mizen top (fifty feet above water) with the first lieutenant, and saw that the luminous waves or pulsations were really travelling parallel to each other, and that their apparently rotatory motion, as seen from the deck, was caused by their high speed and the greater angular motion of the nearer than the more remote part of the waves. The light of these waves looked homogeneous, and lighter, but not so sparkling, as phosphorescent appearances at sea usually are, and extended from the surface well under water; they lit up the white bottoms of the quarter-boats in passing. I judged them to be twenty-five feet broad, with dark intervals of about seventy-five between each, or 100 from crest to crest, and their period was seventy-four to seventy-five per minute, giving a speed roughly of eighty-four English miles an hour.

From this height of fifty feet, looking with or against their direction, I could only distinguish six or seven waves; but, looking along them as they passed under the ship, the luminosity showed much further.

The phenomenon was beautiful and striking, commencing at about 6h. 3m. Greenwich mean time, and lasting some thirty-five minutes. The direction from which the luminous waves travelled changed from south-south-west by degrees to south-east and to east. During the last five minutes concentric waves appeared to emanate from a spot about 200 yards east, and these meeting the parallel waves from south-east did not cross, but appeared to obliterate each other at the moving point of contact, and approached the ship, inclosing an angle about 90°. Soundings were taken in twenty-nine fathoms; Stiffe's Bank, with fifteen to twenty fathoms, being west about one mile. The barometer was already at 29·25 from 8 to 12 P.M.

	At 8 P.M.	10.15 P.M.	Midnight.
Temperature of air ...	84 ...	83 ...	83
Temperature of sea-water ...	84 ...	82 ...	82

I observed no kind of change in the wind, the swell, or in any part of the heavens, nor were the compasses disturbed. A bucket of water was drawn, but was unfortunately capsized before daylight. The ship passed through oily-looking fish spawn on the evening of the 15th and morning of the 16th inst.—I have the honour to be, Sir, your obedient servant,

J. ELIOT PRINGLE, Commander

GENERAL RESULTS OF EXPERIMENTS ON FRICTION AT HIGH VELOCITIES MADE IN ORDER TO ASCERTAIN THE EFFECT OF BRAKES ON RAILWAY TRAINS

THE experiments were made on the Brighton Railway, with the assistance of Mr. George Westinghouse, with a special four-wheeled van constructed for the purpose; it was attached to an engine, and was run at various speeds, during which time various forces were measured by self-recording dynamometers. The principle of these dynamometers is that the force to be measured acts on a piston fitting in a cylinder full of water, and the pressure of the water is measured by a Richards indicator connected by a pipe to the cylinder; thus, as the drum of the indicator revolves, diagrams are obtained, giving the force acting on the piston. The advantages of this method are obvious, because the indicator can be placed at any convenient point and the inertia of the water tend to make the pencil keep a position corresponding to the mean force. A detailed description of the construction of the dynamometers has been given in the *Proceedings* of the Institution of Mechanical Engineers, but would occupy too much space in this *résumé* of the experiments.

Brake blocks were applied to both pairs of wheels, but the dynamometers were attached to one pair of wheels only. The greater number of experiments were made with this latter pair of wheels, the second pair being reserved for special experiments when the van was slipped from the engine.

The levers for bringing the brakes into operation were so arranged that the brake blocks were applied on both sides of each wheel, and the pressure was equally distributed between the four brake blocks, acting on the pair of wheels.

The dynamometers above mentioned registered (1) The pressure applied to force the brake blocks against the wheels. (2) The friction which took place between the brake blocks and the wheels, due to that pressure, measured by the effort made by the revolving wheel to cause the blocks to revolve. (3) The weight on the springs over the braked wheels at each moment during the experiment, which, added to the weight of the wheels, axles, and springs, gives the weight for calculating the adhesion. (4) The tractive force exerted by the draw-bar. (5) Two self-recording speed-indicators were used, designed by Mr. Westinghouse, one instrument being attached to each pair of wheels. This instrument has been repeatedly tested, and was used at the brake trials on the North British Railway and on the German State Railways. It consists of a small dynamometer made on the same principle as that just described; it measures the centrifugal force of two weights, which are made to revolve by a strap from a pulley on a shaft driven by friction-gear from the pair of wheels to which the brake was applied; a Richards indicator is used, as with the other dynamometers. As the centrifugal force varies as the square of the velocity, the speed is got by taking the square root of the ordinate at any point of the indicator diagram.

The diagrams from one speed indicator showed the speed of the pair of wheels to which the brake was applied, and therefore the velocity of the train at the moment of applying the brake and subsequently, provided there was no slipping. Any variation in the speed-diagram was due to the wheels slipping, and shows to what extent and in what way the brake acted to stop the wheels. The diagrams from the other speed indicator showed the speed of the unbraked wheels. A Bourdon gauge, with the face divided in such a way that the hand showed the speed in miles per hour, was attached, for convenience, to the Westinghouse speed-indicator. As a check upon these, two of Mr. Stroudley's speed-indicators were fixed side by side in the van; one attached to the axle belonging to the braked wheels, the other to the axle which was running free. These indicators do not record the speed.

The indicators were all placed on a table in the centre of the van, and their drums were made to revolve by the cords being wound up on pulleys on a shaft, which was turned at a uniform rate by a water clock. This clock merely consisted of a plunger sliding in a cylinder through a water-tight packing, and loaded with a heavy weight; it was wound up by connecting it with the accumulator which supplied the dynamometers, and at the beginning of each experiment a small cock was opened which allowed the water to run out and the weight to fall, thereby turning the indicators round at an ascertained uniform speed. Thus, while the ordinates of the diagrams taken from these several indicators show the various forces, the abscissæ show the time occupied in the experiments.

In most of the experiments the tyres were of steel, and the brake-blocks of cast iron. Some experiments were made with wrought iron blocks, but the results were not uniform or satisfactory.

Numerous diagrams were taken with this apparatus, but it will suffice here to give the general results arrived at.

It is convenient in looking at the question of railway-brakes to consider first, what is the operation of a brake?

A train through the adhesion of the wheels of the locomotive acting on the rails, slowly accumulates energy, and for each ton of weight in the train, the accumulated energy is equal to 120 foot-tons at 60 miles per hour, 53 foot-tons at 40 miles per hour, and 30 foot-tons at 20 miles per hour. Thus, for a train of fifteen vehicles, weighing 200 tons, the energy at 60 miles per hour is equal to 24,000 tons falling a distance of one foot.

After a train has attained the desired speed, the reasons for stopping it may be of two kinds: (1) at prearranged places for convenience; and (2) for the prevention of accidents or for mitigating the consequences if accidents are unavoidable.

To stop a train for the first reason requires but a limited amount of force, which may be applied in any crude manner.

For the prevention of accidents, however, there is required:—

a. The instantaneous application of the greatest possible amount of retarding force.

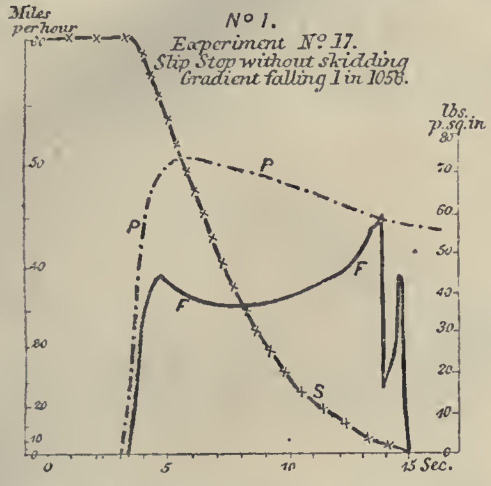
b. The continuous action of this force until the momentum of the train is destroyed.

The retarding force used in practice is that due to the friction resulting from the forcible application of pieces of metals or wood (brake blocks) to the tyres of the wheels; this friction impedes the rotation of the wheels, and tends, through the adhesion of the wheels to the rails, to destroy the energy stored in the train. The retarding force is therefore limited to the resistance obtainable between the wheels and rails.

It was at first customary to attach to a train, for purposes of retardation, a certain number of vehicles with extra weight, to which the brakes were applied; but since the question of retardation has become better understood, brakes have been applied to every vehicle, the means of applying these brakes being placed in the hands of both the engine-driver and the guard. The reason for this is that the maximum amount of retarding force can be obtained only by applying brake blocks to every wheel in the train, each block being pressed with sufficient force to produce a resistance to the rotation of the wheel just equal to the greatest possible friction between the wheel and the rail. This greatest possible friction occurs when the adhesion of the wheel to the rail is just about to be overcome by the superior effort of the brake blocks, which effort, if further increased, immediately begins to stop the rotating movement of the wheel, and thus causes it

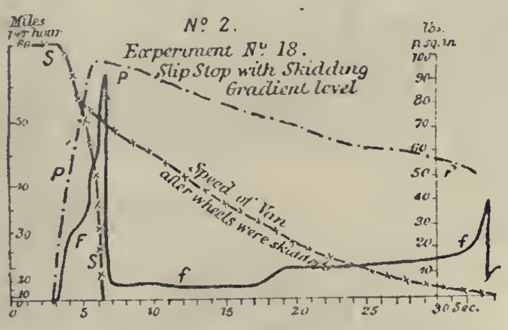
to slide upon the rail. The experiments were made with the object of measuring the force thus brought into action.

The first result of the experiments was to show conclusively that the retarding effect of a wheel sliding upon

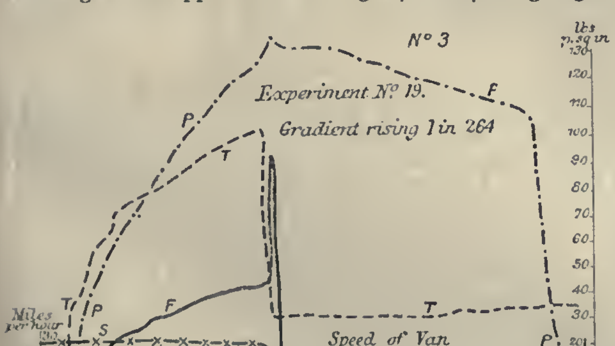


a rail is much less than when braked with such a force as would just allow it to continue to revolve.

The annexed copies of two sets of diagrams (No. 1 and No. 2) taken during the experiments show, more



clearly than can be explained, the difference in the retarding force before the wheels begin to slide upon the rails, and after. These two experiments were made with a single van slipped from the engine, the brakes going on



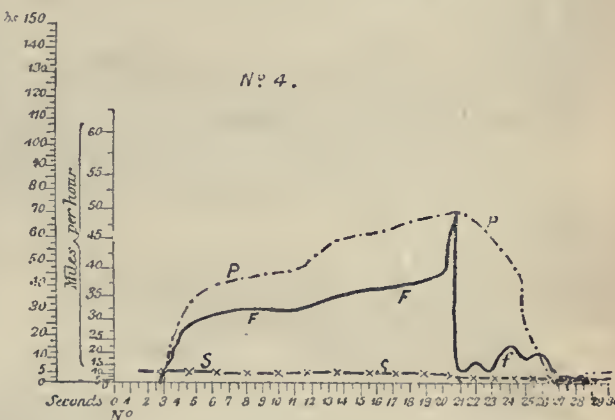
automatically when separation from the engine took place. S is a line showing the speed of the van at each instant, the scale for which is at the left side. P is the pressure against four blocks acting upon one pair of wheels; the vertical height of P by the scale on the right hand multiplied by 240 gives the total pressure in pounds on the four blocks. F is the line showing the retarding effect of the four blocks upon the one pair of wheels before the wheels began to slide upon the rails; and *f* shows the effect while the wheels were sliding upon the rails. The vertical height of F or *f*, according to scale B, multiplied by 60, gives the retardation in pounds. It will be seen that the stop was made in half the time with the wheels braked but not skidded of that required when the wheels were skidded.

The accompanying Diagram 3 shows in another way the comparative retarding effect of the brakes when acting on the revolving wheels and when applied with sufficient force to skid the wheels.

This experiment was made by keeping the van at a uniform speed on a rising gradient of 1 in 264—the line T shows the strain on the draw-bar during the experiment. The line S shows the speed of revolution of the braked wheels, when the revolution was checked and the friction diminished as shown by the line *f*; the strain, T, on the draw-bar diminished in a corresponding ratio.

From this it is evident that the retardation which arises when the wheel is sliding on the rail is far less than the retardation produced by the effect of the brake blocks when applied to the wheels so as to allow the wheels to continue revolving.

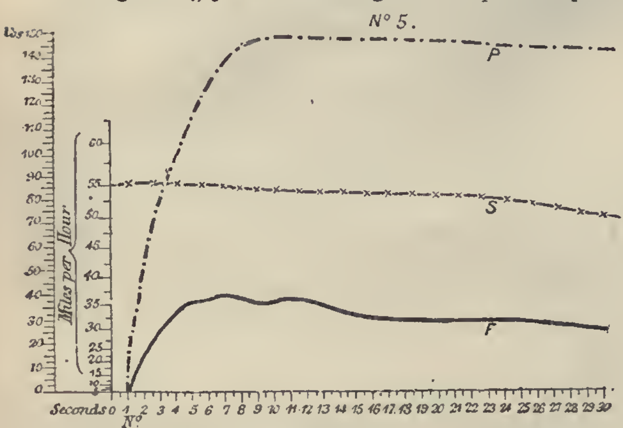
In order to understand this it is necessary to consider the general action of railway brakes. When a train is



moving at a given velocity the adhesion of the wheels on the rails causes them to revolve; every point on the surface of the tyre moves round at the same rate as that at which the train itself is moving forward; but every such point in relation to the forward movement of the train comes successively to rest at the moment when it comes in contact with the rail. Now when the brake is applied with a slight pressure only, the wheel continues to move round at the same rate as that at which the train is moving, but it moves with more difficulty, and this increased difficulty in moving is shown either by an increase in the tractive force required to keep up the forward motion, or, in cases where the accelerating force is not kept up, by the tendency of the moving mass to come to rest in a shorter time than would otherwise be the case. But if the pressure with which the brake is applied be increased, a point is reached when the friction between the brake block and the wheel first approaches, then equals, and finally exceeds, the adhesion of the wheel on the rail. When this happens, the wheel first begins to revolve more slowly, and then ceases to revolve and slides along the rail, or, as it is usually termed, is skidded. The retardation is then no longer due to the friction between the brake block and the tyre of the wheel; but the vehicle is transformed for the time from

a vehicle on wheels into a sledge, and the retardation is due to the excess of resistance which is produced by making the vehicle slide along the rails over that produced by making the vehicle move forward on wheels revolving freely.

The reason why the retardation caused by the brake blocks applied to revolving wheels exceeds that caused by the skidded wheels became obvious from the fact next discovered, viz., that the coefficient of friction between the brake blocks and the wheels varied inversely according to the speed of the train, a higher proportionate percentage of brake-block pressure being required to obtain a given amount of friction at high speeds, and a lower pressure at lower speeds. This is illustrated by the Diagrams 4, 5. In these diagrams P represents pres-

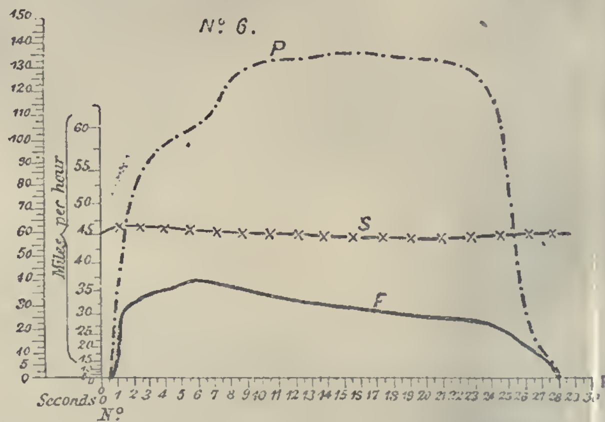


sure, F friction, and S speed, measured on the respective scales at the side to be corrected by the multiple before mentioned; it will be observed that the ratio of F to P in Diagram 4 with a speed of eleven miles per hour is much larger than that of F to P in Diagram 5 with a speed of fifty-five miles per hour.

The following table shows the coefficient of friction obtained from these experiments at varying speeds between cast-iron brake blocks and steel tyres:—

No. of experiments from which the mean is taken.	Velocity.		Coefficient of friction.		
	Miles per hour.	Feet per second.	Extremes observed.		Mean.
			max.	min.	
12	60	88	·123	·058	·074
67	55	81	·136	·060	·111
55	50	73	·153	·050	·116
77	45	66	·179	·083	·127
70	40	59	·194	·088	·140
80	35	51	·197	·087	·142
94	30	44	·196	·098	·164
70	25	36½	·205	·108	·166
69	20	29	·240	·133	·192
78	15	22	·280	·131	·223
54	10	14½	·281	·161	·242
28	7½	11	·325	·123	·244
20	Under 5	Under 7	·340	·156	·273
	Just moving		—	—	·330
Fleeming Jenkin		·0002 to ·0086	·337	·365	·351
Static friction (Rennie) 180 lbs. per square inch		—		—	·300
336 lbs. per square inch		—		—	·347

If the position of the brake-blocks were always the same at the same speed, some simple rule might be deduced which would give the pressure required at each speed for obtaining a certain amount of retardation; but when the speed of the van was kept nearly uniform by the effort of the engine, the friction of the blocks decreased; and this occurred notwithstanding a continued increase of the brake-block pressure: showing that, through some cause not yet fully determined, the holding-power of brake-blocks at all speeds is considerably less after some seconds of application than when first applied. This peculiarity is illustrated by Diagram 6, and is also



apparent in Diagram 5. Hence the question of the proper amount of brake-force needed at each instant, during the time required to stop a train, is still further complicated by this decrease which occurs in the coefficient of friction after the brakes have been applied, and which results from the time during which they are kept applied, irrespective of any change in speed. This decrease in the coefficient of friction is shown in the following table:—

Coefficient of Friction as affected by Time

Speed. Miles per hour.	Coefficient at commencement of experiment.	After 5 seconds.	After 10 seconds.	After 15 seconds.	After 20 seconds.
20	·182	·152	·133	·116	·099
27	·171	·130	·119	·081	·072
37	·152	·096	·083	·069	—
47	·132	·080	·070	—	—
60	·072	·063	·058	—	—

Diagram 7 shows the curves of this decrease obtained from a few of the experiments. It would seem as if the coefficient of friction due to each speed becomes nearly uniform after a certain number of seconds have elapsed. The experiments were, however, necessarily limited to something between twenty and thirty seconds each, so that this point has not been fully determined.

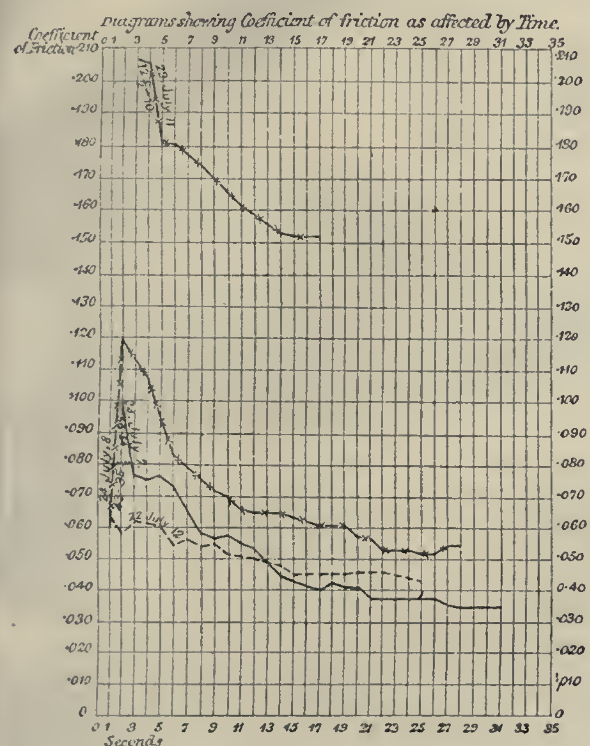
The decrease in the coefficient of friction, arising from time sometimes overcomes the increase in the coefficient of friction arising from a decrease in speed; especially when, either from the stop being on a descending gradient or from a small proportion of the train only being fitted with brake power, the train takes considerable time in coming to rest. Therefore, a higher brake pressure is required in such cases than when the stop is made in a short time.

The accompanying diagram (8) shows a uniform force of friction with a practically uniform speed, as obtained by means of an increasing brake-block pressure. The line P, shows the pressure, F the friction, and S the

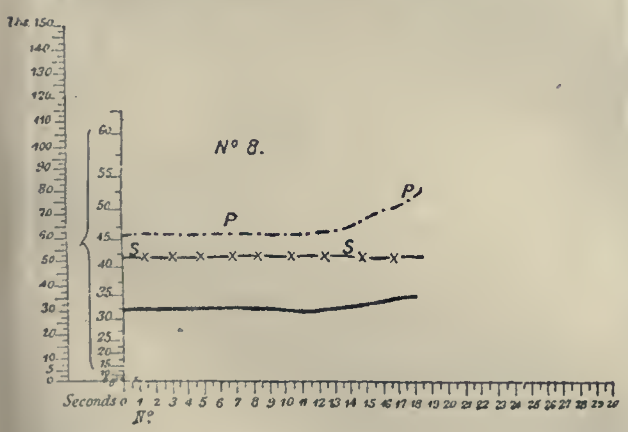
speed, which decreased slightly during the experiment, and would have caused an increase in the coefficient of friction had it not been counteracted by the element of time.

There is nothing unnatural in the fact that friction decreases with speed. Friction is mechanical work; it re-

Nº 7.

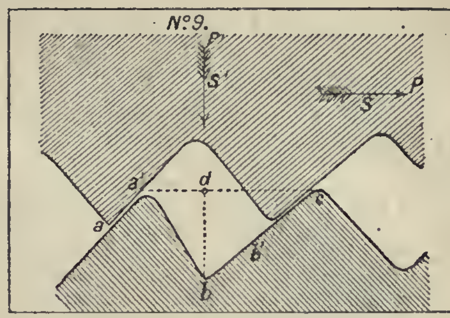


quires a definite force to move a body which is in contact with another, and such movement causes a perceptible wear of the surfaces in contact. The manner in which this work is accomplished can be explained only by the fact that the surfaces in contact are not perfectly smooth, but irregular, although this irregularity may not be distinctly visible to the naked eye. These surfaces, if exa-



mined under a sufficiently strong microscope, would be found to be somewhat as represented in the accompanying diagram, No. 9.

If the upper body be moved in the direction of the arrow, S, by a force, P, the point, *a*, of the upper surface would mount the incline, formed by the corresponding portion of the lower body, until it reached its summit at *a′*; from this moment it would begin to descend the next incline, from *a′* to *b*; provided the force, P, acting in the direction of the arrow, S, would leave it time to do so, the incline from *b* to *c* would have to be mounted next, causing a certain amount of resistance during the time the body traversed the distance *d c*. But if we increase the speed in the direction of the dart S, so that the body will require less time to traverse *a′ d* than to fall through *d b*, in such case *a′* would not arrive at *c*, but at some other point, *b′*, and then only the portion of the



incline *b′ c* would have to be mounted, presenting a smaller amount of resistance than in the former case. This illustrates what occurs.[1]

The fact that the coefficient of friction diminishes with speed sufficiently explains why a skidded wheel affords less resistance than one which still rotates, because the resistance occasioned by the rotating wheel is only limited by the adhesion of the wheel on the rail, and this, as already shown, is the same as static friction, since the point of the wheel is stationary as regards the forward movement of the train at the moment it touches the rail; whilst when the wheel is skidded and slides, the friction is that due to the speed at which the wheel moves on the rail, and is therefore less than the other.

DOUGLAS GALTON

(*To be continued.*)

GEOGRAPHICAL NOTES

ON Monday the French Geographical Society held an extraordinary meeting, in the large hall of the Sorbonne, for the reception of Major Serpa Pinto, the African explorer. We understand that Major Serpa Pinto and Lieut. Lucien N. B. Wyse have both promised to attend the coming meeting of the British Association at Sheffield, and will give accounts of their recent explorations in Africa and the American Isthmus. Some other very interesting papers, we hear, are in preparation for the geographical section, over which Mr. Clements R. Markham will preside.

THE principal novelty in this month's Petermann's *Mittheilungen* is an elaborate paper "On the Geographical Distribution of some Plague Epidemics," by Dr. Carl Martin. Dr. Emin Bey has a short paper "On the River Obstructions of the Bahr el Jebel," and we regret to say, Dr. Gerhard Rohlfs writes from Bengazi on June 10, that he has resigned the leadership of the expedition of the German African Society, which was organised for the purpose of reaching the Congo by starting from Tripoli. Dr. Rohlfs gives as his chief reason for resigning, the length of time the expedition is likely to last, and the value of even a single year at his age. He has, however, done his best to remove all difficulties from the way of the expedition in setting out, and these have not been few. He proposes Dr. Stecker to succeed him, and hopes the

[1] This simple illustration is taken from an article in the *Chicago Railway Gazette*, by M. Krajewski.

Society will approve. Though Dr. Rohlfs' resignation is to be regretted, he cannot be blamed, and we trust the expedition will be able to carry out its original programme.

THE French Government will present to their Parliament a bill for taking preliminary steps in order to establish a Soudan railway from Algiers to Senegal, *viâ* Timbuktu. An official commission has been appointed to report on that subject.

THE *Engineering and Mining Journal* states :—At a late meeting of the New York Academy of Sciences, Prof. Arnold Guyot, of Princeton College, presented before the Geological Section a paper upon "The Topography of the Catskills," containing the results of several years of study of these mountains, and which he is about to publish. From the contents of this interesting paper, it will appear, that this region of country—in the midst of the oldest settlements, and long celebrated as a summer resort—has remained comparatively an unknown wilderness, even to this day; for Prof. Guyot, within the past few summers, has actually discovered and named an extensive group of mountains rising into peaks in some cases over 4,000 feet high (the "Southern Catskills," or "Shandakeens"), which are not laid down on any map, or described in any gazetteer. These works of reference refer to this region as "a hilly country," merely, and the fact that it contains mountains higher than the true Catskills, is quite new to science, and it has been reserved to Prof. Guyot to make an interesting geographical discovery in the very heart of the State of New York. For the paper *in extenso* our readers are referred to the *Proceedings* of the Academy, and for a fuller abstract, to the *American Naturalist* for July, to which we are indebted for the brief notice here given.

CAPT. JAMES B. EADS, who is constructing the jetties to deepen the channel at the mouth of the Mississippi River, has written a letter to the *New York Tribune*, in which he proposes to substitute for the contemplated ship canal across the Isthmus of Darien a railway by which the largest vessels may be conveyed across in twenty-four hours. This project he claims to be entirely practicable, and says it would cost considerably less than the canal, and might be completed in three or four years. The ship could be raised by a lock and the usual hydraulic methods, and he suggests two methods that are practicable, and with precautions to prevent straining. He recommends turn-tables instead of curves in the railway where changes of direction are necessary. The car, or cradle, to carry the ship should be built in sections, each about 100 feet long, and each section supported by about 200 wheels, some of them driving wheels moved by engines. The weight of the largest merchant steamers and their cargoes would not exceed 10,000 tons. Such a vessel Capt. Eads would place on five of these sections, supported by 1,000 wheels bearing on eight or ten rails, so that each wheel would support about 12 tons. He thinks his plan entirely practicable, and urges it very strongly. Indeed the scheme adopted at the recent conference for an interoceanic canal meets with no favour in America, and Mr. Troutwine thinks it will never be finished, the difficulties are so great. Perhaps national, as much as engineering reasons, influence American opinion on the subject.

DR. H. A. A. NICHOLLS, who, we believe, is Surveyor-General of Dominica, has addressed to the *Colonies and India* some notes of considerable interest on that little-known island and its boiling lake. In many parts, he tells us, fine undulating uplands extend from the heads of the valleys far into the interior, and one runs across the broadest part of the island at an elevation of 800 feet above the sea, containing many thousands of acres of fine, well-watered land, with a virgin forest of lofty timber trees. The chief mountain peak reaches a height of 4,747 feet. Only a small portion of the island is cultivated, but of the rest, which is covered with the primeval forest, large tracts are suited for the growing of coffee, cocoa, spices, limes, and other tropical products. The Boiling Lake, which is at an elevation of 2,425 feet above the sea, has been visited on three occasions by Dr. Nicholls, who, on his second visit, ascertained that the temperature at the edge was 180° F., gradually increasing towards the centre. The lake was first seen in recent times by an exploring party organised and led by Mr. Watts, a colonial magistrate, and Dr. Nicholls. They thought they were its discoverers, but it has been found that the volcano is mentioned in a very rare medical work published in 1797.

PROF. GEORG GERLAND concludes in the current number of *Globus* a long and elaborate examination into the future of the American Indians. The conclusion he comes to is that facts do not warrant the inference that the Indians are dying out, nor that they have been deleteriously affected by contact with civilisation.

IN the course of this month a highly interesting geographical work will be published by Karl Graeser, of Vienna, by order of the Austrian Minister for Education. Its author is Prof. Friedrich Umlauf, and its title "Wanderungen durch die oesterreichisch-ungarische Monarchie; landschaftliche Characterbilder in ihrer geographischen und geschichtlichen Bedeutung."

THE second International Congress for Commercial Geography will take place at Brussels from September 27 to October 1 next. It will be divided into five sections; the first will consider commercial routes and exploring expeditions, the second natural and artificial products, the third and fourth questions relating to emigration, colonisation, and instruction, while the fifth section will be devoted to the discussion of general questions.

HERR CARL BOCH, who has now finished his natural history exploration of the western highlands of Sumatra, is about to explore, on behalf of the Dutch Government, the north-eastern part of Borneo—the district of Koetai. There is a powerful and friendly Sultan at Koetai, who has been requested by the Dutch Government to give all possible assistance to Herr Boch.

ONE of the newest of French geographical societies, that of Montpellier, which has assumed the title of Société Languedocienne de Géographie, now publishes a *Bulletin* about every two months, which for size is imposing enough, for the last number runs to 180 pages. It contains, among other matter, observations on the creation of an inland sea in the Eastern Sahara, and papers on Natal, the Transvaal, and Zululand, and on the River Ogowé, as well as a summary of M. Soleillet's account of his recent attempt to reach Timbuktu, *viâ* Ségou.

A NEW project for the construction of a system of canals connecting the Caspian Sea with the Black Sea is now being considered by the Russian Government, and is discussed in a recent number of the *Journal* of the Russian Imperial Office for Public Works of Communication. The author of the new project is the engineer, M. A. Daniloff. He proposes to construct (1) a canal of some 300 versts in length, from the River Terek to the water-shed of the River Manytsch, which connects the Don with the Caspian Sea, but the bed of which is generally dry; (2) a canal of about 320 versts, from the mouth of the River Kalans (a tributary to the Manytsch), eastward to the Wolga, near Astrachan; (3) a canal from the same spot, westward to the Don (about 350 versts); (4) a branch from the eastward canal to the Serebriakowskaya Station on the Caspian Sea; (5) a branch from the westerly canal to the Black Sea. Other Russian news states that the Government has commanded the Khan of Khiva to furnish 5,000 workmen for the works connected with directing the Oxus River into the Caspian Sea.

PROF. MOEBIUS ON THE EOZÖON QUESTION[1]

II.

HAVING described the Eozöon sufficiently to enable the reader to follow its comparison with foraminifera, Prof. Moebius proceeds to the description of the structure of these animals. Fig. 12 represents a longitudinal section of *Tinoporus baculatus*, magnified 150 times. This foraminiferal species occurs very frequently upon the coral reefs of the Samoan Islands in the Pacific. Its shell consists of a bi-convex middle part, from which at

FIG. 12.

least four or five spines radiate, all of which are situated in the principal plane of the body of the shell. At C two shells of *Tinoporus* are drawn, magnified three times.

[1] Continued from p. 275.

In the centre of the larger figure we see the globular germ-chamber of the animal (K*a*) round which the next

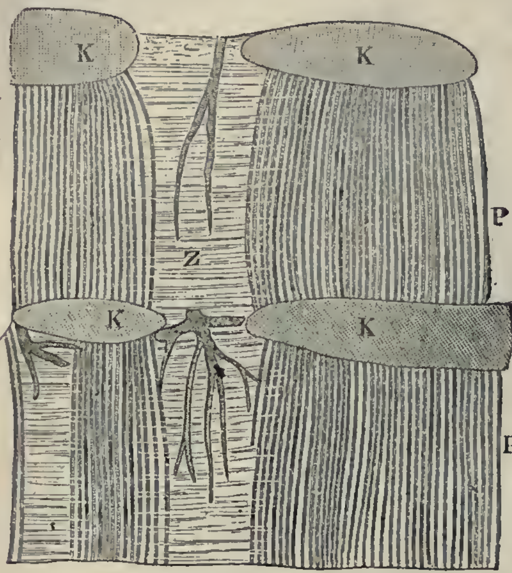


FIG. 13.

FIG. 14.

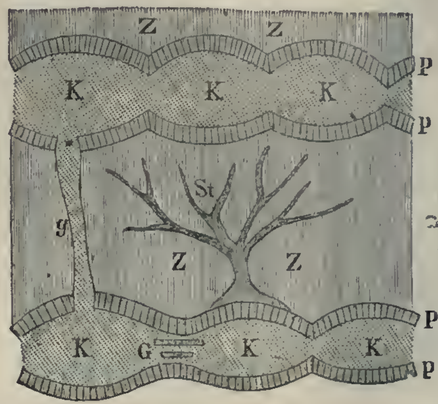

FIG. 15.

following chambers (K) are spirally arranged. Then in four directions curved rows of chambers (K) are formed, which are separated by intermediate matter (Z). The chambers communicate with each other, partly by round passages (G), partly by pore-canals (P). Through the intermediary matter (Z) a canal-system is extended, which in the long arms of the shell ends in many minute canals opening to the surface (K*l*). Through the pores of these little canals, as well as through the orifices of the peripheric pore-canals (P) of the outer rows of chambers, the sarcode, *i.e.*, the gelatinous body-substance of the animals, is in communication with the outside. In some parts protruded, granular sarcode filaments are represented (S, S); these are the so-called pseudopodia. At C we see two chitinous chamber-linings with adherent linings of pore-canals, magnified 350 times; at *d* are drawn chitinous ducts from the canal-system in the intermediary matter, also magnified 350 times, and freed from lime by treatment with dilute chromic acid. Fig. 13 represents a small part of a cross section of a tertiary *Nummulina*, magnified 220 times. K K are the chambers which were filled with sarcode. The superposed chambers communicate by means of pore-canals (P P). Between the chambers there is a deposit of poreless intermediary matter (Z), into which ramified canals are penetrating. Fig. 14 shows five pore-canals, magnified 500 times. Here it is seen distinctly that they are round tubes separated by calcareous matter. Some of them are partly filled with a dark material.

According to Dawson and Carpenter the limestone of the Eozöon represents the shell of the Eozöon animal, and the serpentine the material filling the chambers. Thus the serpentine now takes the place of the sarcode which once lived in these chambers, and which from its substance secreted the lime as a shell. The serpentine patches of the fossil Eozöon, according to this view, have the same shape and size which the separate chamber bodies of the living animal possessed when fully extended.

The separate fibres of the bands lying between the limestone and the serpentine, according to Dawson and Carpenter, are the siliceous fillings of the minute canals through which the sarcode body could send pseudopodia-filaments into the water outside of the shell. The simple

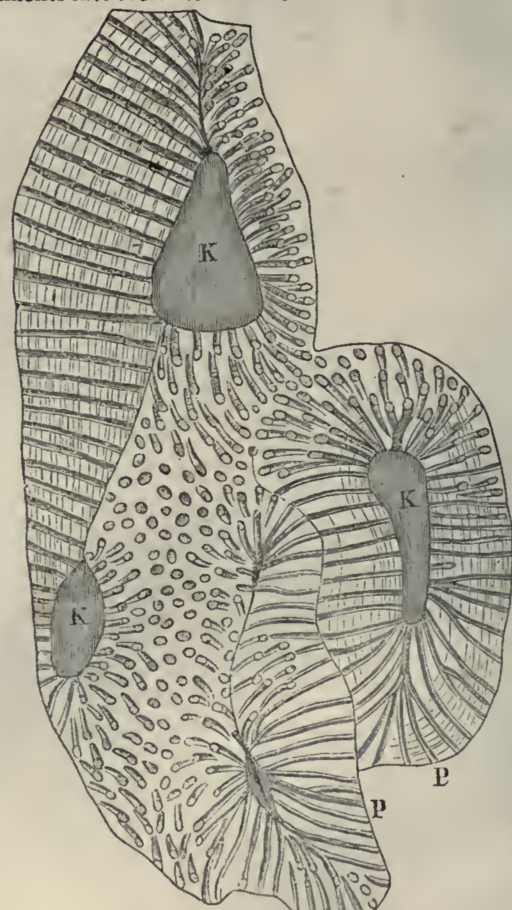

FIG. 16.

and the ramified stems in the limestone are siliceous

fillings of canals in which the Eozöon sarcode extended through the calcareous intermediary matter.

Dr. Carpenter represents this view of the different parts of Eozöon by a systematic drawing, which we give in Fig. 15. K, K, K are two rows of chambers filled with serpentine. The narrow parts between the chambers correspond to the round passages of foraminifera. In the lower row of chambers, at G, the communicating passage between two chambers is divided into three narrow ducts by two plates which lie embedded here. P, P represent the walls of the chambers penetrated by the fine pore-canals, in the places of which in the real Eozöon fibres of chrysotile are now situated. Z, Z is the intermediary matter of the Eozöon shell, into which the ramified canals (St) (the present stems of the Eozöon) are protruding. Towards the left, at *g*, a chamber duct is represented, which unites two chambers of different rows or layers. Chamber ducts of this kind occur in *Tinoporus baculatus* (Fig. 12), for instance, and also in other living foraminifera.

Prof. Moebius then proceeds to compare one by one the different parts of Eozöon with those parts of foraminifera to which, according to the views of Dawson and Carpenter, they are supposed to correspond.

1. If the patches of serpentine are the filling materials of the Eozöon chambers, then they represent their cavities plastically in a similar way, as the stone kernels of echini, gasteropoda, and ammonites represent the interior cavities of the shells of these animals.

The relative sizes of the serpentine patches vary very much. The longitudinal axes of the largest ones are about thirty times as large as those of the smallest. Their absolute sizes vary from a few millimetres in length and 0·5 mm. in height, to 20-30 mm. in length and 5–10 mm. in height.

The serpentine patches of Eozöon are in form and arrangement, as well as in relative size, very unlike the chambers of most foraminifera. In their shapes none of the fundamental forms are reproduced again and again, which in all the chambers of a foraminifera species point back to one and the same law of formation. Neither the fundamental shape of a ball or lentil, nor the shape of a crescent or sickle, which occur in the different foraminifera species, form the basis of the serpentine patches of Eozöon. Yet there is a certain regularity in their shape and arrangement. Frequently they have contours similar to crystals of olivine (Fig. 10). Generally they form concavo-convex layers which are superposed and are separated by layers of limestone (Fig. 1). In many pieces an increase in size of adjacent serpentine patches in one direction may be observed. In many others ball-shaped or oval serpentine patches are arranged in such a manner that they form a spiral (Figs. 3 and 4). But this arrangement does not give the impression of a *genetic* succession, as is the case with the chambers of spiral foraminifera.

2. The fibres, forming band-like spaces between the serpentine and the limestone are supposed to be the siliceous fillings of fine pore-canals which penetrated the calcareous chamber-walls of the Eozöon shell.

Fig. 17.

The pore-canals in the chamber-walls of foraminifera are cylindrical tubes, separated by calcareous intermediary matter. Thus every tube runs *isolated* through the chamber-wall (Figs. 12, 13, and 14). The fibres of the Eozöon, however, are prismatic needles or little plates, which are situated close together (Figs. 10 and 11), and

Fig. 18.

therefore they cannot represent the fillings of cylindrical tubes in another material. In no sections, neither in those which cut through them at right angles, nor in others which exhibit them obliquely, nor in those which are parallel to their axis, any traces of an intermediary substance separating the single fibres can be found. Also in polarised light the fibre bands appear altogether homogeneous and consisting only of *one* kind of material.

The pore-canals penetrate the chamber-walls of the foraminifera in such a direction that to the sarcode filaments, which, as pseudopodia are sent forth from the chambers into the water outside, they offer the shortest possible way (Figs. 12 and 13). Thus as a rule they lie at right angles to the inner and outer surfaces of their

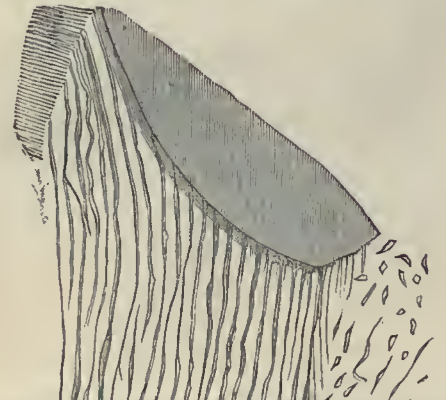

FIG. 19.

chamber-wall, as long as this continues to get uniformly thicker by the deposition of regular layers. If the thickening of the chamber-walls takes place in an irregular manner, then it often happens that the pore-canals are curved; yet even in this case the tendency of the sarcode to reach the outside water through the new thickening layers of its chamber-wall by the shortest possible way becomes apparent. This law is manifest even with the simplest forms of foraminifera, the chambers of which are not even of regular shape and arrangement. Fig. 16 illustrates this; it represents a section of *Carpenteria rhaphidodendron* magnified 120 times; K K are chambers, P P pore-canals.

In the direction of the Eozöon fibres, which are supposed to correspond to the pore-canals of foraminifera, a similar organic regularity is altogether missing. It is true that in many places they radiate from the surface of the serpentine patches, which are supposed to be the fillings of foraminifera chambers, at right angles towards the limestone; yet the direction of the fibres in these places cannot be said to represent the direction of the sarcode of a foraminifera species, because in adjacent parts the direction of the fibres does not always obey the same law, and because for great distances in the fibre bands all the fibres retain a parallel direction, no matter whether they lie at right angles, obliquely, or even tangentially to the serpentine patches. This is shown in Fig. 17, representing a section of Eozöon magnified ninety times; in the centre is a serpentine patch, S, surrounded almost on all sides by parallel chrysotile prisms; above to the right there is a smaller patch of serpentine, surrounded by chrysotile fibres of the same direction. The pseudopodia of a living sarcode mass, which once took the place of the serpentine, cannot therefore have determined the direction of the fibres; on the contrary, their parallelism points to an *inorganic* origin, because it is independent of the curvatures of the boundaries between serpentine and limestone.

3. The stems in the limestone of the Eozöon are supposed to be the siliceous fillings of ramified canals in the intermediary matter of the Eozöon shell. In good sections the stems generally look brownish in transmitted light; whitish or colourless ones are much less frequent. Their shape, size, direction, and quantity vary extremely, not only when different sections are compared, but very often already in different parts of the same section, even if this measures only a few millimetres in length and breadth. The stems may lie so close together that the spaces intervening are hardly larger than their own diameters (Fig. 18); often they are separated by wide intervals (Figs. 5 and 18). Sometimes they run parallel (Fig. 18), at other times they radiate from one or more points, or assume the shape of feathers (Fig. 19). They touch the boundaries of the limestone or are imbedded in the midst of this (Figs. 5 and 18); they are simple (Figs. 18 and 19) or ramified (Figs. 5, 9, 10, and 18), long and slender or short and broad. They terminate in fine points or in the shapes of clubs or spoons. They are straight, bent into knee shapes, curved like waves, or folded and twisted irregularly.

Their sections generally have sharp edges; round or elliptical sections, like those of the ramified canals of foraminifera, are rare amongst them. The sizes and shapes of successive sections of one and the same stem may also vary considerably.

Prof. Moebius concludes his treatise with the following characteristic sentences:—"My task was to examine Eozöon from a biological point of view. I commenced it with the expectation that I should succeed in establishing its organic origin beyond all doubt. But facts led me to the contrary. When I saw the first beautiful stem-systems in Prof. Carpenter's sections, I became at once a partisan of the view of Professors Dawson and Carpenter; but the more good sections and isolated stems I examined, the more doubtful became to my mind the organic origin of Eozöon, until at last the most magnificent 'canal-systems' taken all together and closely compared with foraminifera sections preached to me nothing but the inorganic character of Eozöon over and over again.

"In the minds of other zoologists, while showing them a series of my finest Eozöon sections, stem preparations, and foraminifera sections under the microscope, I have repeatedly in the course of an hour called forth these mental metamorphoses, which I passed through in the course of a long period of investigation.

"I am heartily sorry that, by way of thanks for the extremely kind support which Professors Dawson and Carpenter have given me in these investigations by

sending me beautiful Eozöon pieces, I cannot say to them: According to my investigations also *Eozöon canadense* must be regarded as a fossil species of foraminifera. I am convinced that both, like myself, had the honest intention to represent correctly the true nature of Eozöon. But they must own that in their descriptions they did not investigate so closely nor describe so minutely the shapes nor the relative positions of the various parts, as I have done in my treatise. If they had done this then I believe that the facts would have led them to the same conclusions which they forced upon me.

"If the Eozöon pieces from the Laurentian or 'Urgneiss' formation were really remains of an undoubted foraminifera species, then we should possess in them *certain* proofs that even during the formation of the most ancient strata of the earth's crust living beings occurred, and that the first organisms belonged to the lowest animals, by which biology and geology would have gained two highly important facts. Yet by the scientifically justified elimination of Eozöon from the domain of organic beings it is not proved that during the Laurentian period no living beings existed. Perhaps the graphite of the Urgneiss formation has its origin in organic beings.

"The proof that Eozöon is not a fossil rhizopod will perhaps for many persons take away an important link from the beautiful picture of the development of organic life upon the earth, which they may have drawn up for themselves. But the object of natural research does not consist in finding reasons for attractive conceptions about nature, but in knowing nature as it really is. Because only an insight into the real condition of nature can, in the long run, satisfy the scientific mind, which gives up as errors the most attractive hypotheses regarding the essence and action of nature, if in the face of newly discovered facts they can no longer hold good, no matter whether these erroneous hypotheses may have reigned supreme for a long time previously, and may have been held to be the best conceptions of nature by the most eminent authorities."

THE BLOWPIPE CONE-SPECTRUM, AND THE DISTRIBUTION OF THE INTENSITY OF LIGHT IN THE PRISMATIC AND DIFFRACTION SPECTRA

NOW that the optical properties of the blowpipe blue cone have been so critically investigated, may I draw the attention of the readers of NATURE who are interested in the history of spectrum analysis, to what I think are the earliest experiments on that subject. They were published by me in 1848. The memoir in which they are reprinted may be found in my "Scientific Memoirs." It contains a woodcut of the five rays, adjusted to a reference solar spectrum on page 64, and another of the five images of the cone on page 69.

Let me also refer to some experiments I have recently made on the distribution of the intensity of light on the spectrum, by the aid of a new form of spectrometer, which depends on the well-known optical principle, that a light becomes invisible when it is in presence of another light about sixty-four times more brilliant.

In a memoir I am now publishing in the *American Journal of Science*, and which, I presume, will also appear in the *Philosophical Magazine*, I have described several modifications of this instrument. The following is one easily made:—

Remove from the common three-tubed spectroscope its scale-tube, and place against the aperture into which it was screwed a glass ground on both sides. In front of this arrange an ordinary gas light attached to a flexible tube, so that its distance from the ground glass may be varied at pleasure. This light I call the extinguishing light. On looking through the telescope-tube the field of view will be found uniformly illuminated, this being the use of the ground glass, the light of which is reflected from the prism. The brilliancy of the field depends on the distance of the extinguishing light from the ground glass, according to the ordinary photometric law.

Now, if another small gas flame be set before the slit of the instrument, on looking through the telescope its spectrum will be seen in the midst of a field of light. If the illumination of that field be made very brilliant, the spectrum will be extinguished; if feeble, all the coloured regions appear. By moving the extinguishing flame to proper distances, it will be found that the violet region is the first to disappear, the red the last. The yellow by no means resists longest, as it ought to do if it were the most brilliant. Hence it follows that in the prismatic spectrum, the red and not the yellow is the brightest ray.

If the cause of the increasing intensity of light in the prismatic spectrum, from the more to the less refrangible region, be the compression exercised by the prism on the coloured spaces, increasing as the refrangibility is less, we ought not to find any such peculiarity in the diffraction spectrum. In this the coloured spaces are arranged uniformly, and without compression in the order of their wave-lengths. An extinguishing light ought to obliterate them all at the same moment.

Having modified the common spectroscope by taking away its dark box, so that the slit-tube and the telescope tube could be set in any required angular position to each other, I put in the place of its prism a glass grating, inclined at 45° to rays coming in through the slit. The ruled side of the grating was presented towards the slit. Now when the extinguishing flame was properly placed before its ground glass, the plane face of the grating reflected its light down the telescope-tube. In this, as in the former case, the spectrum of a small flame before the slit was seen in the midst of a field of light, the intensity of which could be varied by varying the distance of the extinguishing flame. It was now found that as the brilliancy of the extinguishing illumination increased, all the coloured spaces disappeared at the same moment, and on diminishing the illumination all the colours came into view at the same time. As long as the red was visible the violet could be seen.

From this it follows that in the diffraction spectrum the luminous intensity is equal in all the visible regions. In the memoirs now publishing I have applied these facts to the case of the spectrum distribution of heat.

JOHN WILLIAM DRAPER

University of New York

THE NEW THERMO-ELECTRIC LIGHT BATTERY

IT appears that a difficulty which it has long been the ambition of practical electricians to overcome has at last been solved by M. Clamond. According to his statement, published in *La Lumière Electrique*, which is confirmed by the Count du Moncel, M. Clamond has succeeded in producing the electric light by means of his new thermo-electric battery. M. Sudré has also just published his design for a powerful thermo-electric battery, but we do not know whether this system has yet been put to any practical trial, whereas that of M. Clamond is now in actual use for the purpose of lighting certain factories in Paris. Full details of either system have not yet come to hand, so that it is only possible to state the general results at present obtained.

That heat could be transformed into electrical energy was first discovered by Seebeck in 1822, who found that an electric current was produced when the junction of two dissimilar metals was heated. Little use, however, was made of this discovery as a source of energy, owing to the feebleness of the current to which it gives rise, although it has been of great service since the time of Forbes and Melloni in the investigation of radiant heat.

Prof. Bunsen, by the employment of different metals from those hitherto tried, found that he could increase the strength of the current, and M. Marcus, of Vienna, using alloys instead of simple metals for the positive and negative element, reduced the cost, while increasing the power of the battery. From a thermo-electric battery constructed on his principle, and also from a modified form, devised by Wheatstone, a current sufficiently strong to produce brilliant sparks, decompose water, &c., was obtained. This was in 1865, and but little progress has, until now, been made in this branch of science, with the exception of the improved forms of thermo-pile devised by Noë and by Messrs. C. and L. Wray, although the utilisation of heat—especially solar heat—for the production of electricity has long attracted the thoughts of many experimenters.

M. Clamond has for some time been at work upon the subject, and has so far succeeded that his thermo-electric battery has been employed since 1875 in M. Goupil's factories. These batteries are formed of iron, as the electro-positive element, and an alloy of antimony and zinc for the negative; they are soldered together and arranged in a circular form, which can be built up as high as may be desired. The junctions of the metals are heated in the interior, but the electromotive force being proportional to the difference of temperature between the two extremities of each bar, it was necessary to make the bars long if a strong current was desired, and then the results were less satisfactory, owing to the increased internal resistance, the melting of the metals where they were soldered, &c.

It is these hindrances to its extended use which M. Clamond has sought to obviate in his latest form of battery, which is composed of three distinct parts. The *collector* consists of a number of pieces of cast-iron so arranged that the heated air can circulate within them; a large surface is thus exposed to the heat, which the iron collects and communicates to the couples. The *diffuser* is the outside of the apparatus, and is made of sheets of metal. The *thermo-pile proper* is placed between these two, and is so arranged that the junctions of the metals are alternately at the temperature of the collector and the diffuser. Heat passes from the collector to the diffuser along these couples, which have no great length. In some forms which are very easily worked, a number of these couples are made into a flexible chain of any desired length, the extremities forming the poles of the battery. These chains, insulated from the other parts of the apparatus, can be united to each other by their free ends, so that a variety of couplings and combinations may be made. The model now in use for lighting a workshop in Paris is about 2½ metres high, and 1 metre in diameter, the exterior form being that of a polyhedron, to the sides of which the thermo-electric chains are attached; these are composed of small cubes of zinc and antimony joined together by plates of tin, to which they are soldered. Each half of the apparatus has 30 chains of 100 couples each, or 6,000 couples in all. To the outer surface of these chains are fixed the sheets of copper which form the diffuser or heat distributor.

Another model, made for the recent exhibition at the Albert Hall of the various systems of electric lighting, is square and much smaller, though of the same power.

Each half of the cylindrical battery can be made to supply a powerful electric light, while the square one can produce *four* lights of half the brilliancy. The electromotive force is, according to prolonged experiments, 218 volts, about equal to 120 Bunsen cells, while the resistance is 31 ohms. The large battery consumes only 9 or 10 kilogrammes of coke an hour, and the smaller one even less, about 6½ kilogrammes. Moreover, the large exterior surface of the apparatus radiating its heat to the air around adapts it admirably for use in heating, as well as for lighting, and it can thus be made to serve the double purpose of giving warmth and light.

M. Sudré has also designed his thermo-pile with a view to obtaining one of small volume and having a low internal resistance; the other peculiarities of his battery consist in the manner in which one set of junctions are heated while the other set are cooled. He has also determined what is the best length for the bars forming the couples, in order that the necessary difference of temperature at the two extremities may be maintained, while yet making them as small as possible. This he finds should be from 10 to 30 millimetres, according to the difference of temperature required. His manner of soldering together the two different metals is also novel and ingenious. In order that contact may be made with the whole surface of the bar, he cuts the plate, forming one metal, into the shape of a comb, twisting the teeth of this comb together, thus retaining a large surface, which yet has only a short length. The bars are fastened on to these twisted parts and the uncut part of the plate is coated with silicate of soda. The couples are formed in a mould in which the plates are fixed, the melted alloy is then run into the mould so that a block is formed of the alloy and the plates, firmly united. These chains or blocks are then placed between two plates, coated on one side with enamel or other electrically insulating substance; several chains may thus be arranged side by side, each chain being both calorically and electrically insulated. The parts of the chain are electrically insulated by the thickness of the plates, but heat can flow across the couples. The chains are next placed between a collector and a diffuser; the collector is ribbed if the source of heat be gas, in order to expose a greater surface. The diffuser is also ribbed for the same reason when the heat is merely allowed to radiate into the air. The whole battery is so arranged that the collectors form the inside of a circle within which the heated air is circulated.

BIOLOGICAL NOTES

THE BLOOD OF THE LOBSTER.—This liquid has been recently examined by M. Fredericq (Belgian Academy's *Bulletin*, No. 4), whose researches on the octopus were recently published. He finds in it as a rule two colouring matters, one blue, an albuminoid, coagulated by alcohol and heat, and apparently identical with the *hæmocyanine* found in the blood of the octopus; the other of rose colour, and soluble in alcohol (not always present). The former loses its blue colour in vacuo, and recovers it when acted on by oxygen, and it contains copper. The blood of the lobster is rose when it is reduced; exposed to oxygen it takes a special tint, blue with reflected light (hæmocyanine), brown with transmitted light (rose matter). It coagulates spontaneously and therefore contains fibrine. The blood of certain Gasteropoda (*Arion, Helix*) is also found to contain hæmocyanine, whereas M. Fredericq has not found it in the Lamellibranchiata (*Unio, Anodonta*). The general conclusion is reached that in such different groups of invertebrates as cephalopod and gasteropod molluscs, crustacea and annelids, as well as in vertebrates, respiration is effected by means of metalliferous proteic substances (hæmoglobin, hæmocyanine, chlorocruorine) which form in the respiratory organ (branchia, lung) less stable oxygenated combinations. These latter are dissociated in their passage through the tissues. In invertebrates, the two great functions of the blood, respiration and nutrition of tissues, belong both to the plasma, the corpuscles having a quite accessory importance. In the blood of vertebrates there is, in this respect, a division of physiological work; the respiratory function devolves upon the corpuscles, the nutritive function on the plasma.

ANNELIDS OF THE VIRGINIAN COAST.—Mr. H. E. Webster has just published an account of the Annelida Chætopoda which were collected in the summer months of 1874 and 1876 by the zoological expeditions sent out

under the auspices of Union College, Schenectady, N.Y. (in advance of vol. ix. of the *Transactions* of the Albany Institute, pp. 1-72, plates 1-11). The locality was on the eastern shores of Virginia (Northampton); between the mainland and the islands a large area of dark mud is exposed at low water. It is described as abounding in animal life, and yet the number of species of Annelids described is not large, there being only fifty-nine, relegated to forty-nine genera; of these, four of the genera are new, and twenty-seven of the species. The absence of Mediterranean species seems noteworthy, scarcely any of Ehler's species from the Adriatic or Claparède's, from the Bay of Naples, being quoted.

ACID REACTION OF FLOWERS.—It was stated, as the result of observation, by MM. Fremy and Cloëz, that the juices of all red and rose-red flowers showed an acid reaction, whereas the juices of blue flowers were always neutral, or even weakly alkaline. The subject has been studied afresh by Herr Vogel, who examined 100 species, viz., 39 blue, 44 red, 6 violet, 8 yellow, and 3 white flowers. The experiments (described to the Munich Academy) confirm the view that it is not warrantable to attribute the red colouring of flowers to action of acids or acid salts on blue colouring matter, or to attribute the latter to the influence of alkalies on red colouring matter, though doubtless there is a certain relationship between certain red and blue plant colours. It further appears that the opinion that plant juices generally, and even the majority of flower-juices, have an acid reaction, is pretty correct; among 100 flowers there were only twelve which did not react acidly. On the other hand, the rule above referred to is not found to apply universally, for among thirty-eight blue flowers twenty-eight showed a decidedly acid reaction, though the degree of the acidity was less than in red flowers.

FUNCTION OF SOME CONTRACTILE VACUOLES IN INFUSORIA.—An observation recently published by Herr Engelmann, of Utrecht, throws light on the function of the contractile vacuole in some infusoria. Some time ago he found a new infusory animal, closely allied to *Chilodon cucullulus*, and which he calls *Chilodon propellens*; it is marked by its slender form, and by the round shape of its hinder extremity, where is the contractile vesicle. This animal swims with pretty constant, but very slow, velocity in circling paths. Each time the vacuole contracts (which occurs in pretty regular intervals of about half a minute, and very quickly) there is an impulsive acceleration of the forward motion. If the animal be at rest, it makes, at the moment of systole, an impulsive forward movement about a quarter of its length. No simultaneous acceleration of the very sluggish ciliary movement was observed. The forward motion, then, can only be attributed to the backward thrust of liquid expelled from the contractile vacuole. Herewith agrees the fact that the hinder portion of the body shrinks together, in systole, as though to a thin empty sack folded in longitudinal direction, without the least perceptible increase in volume of the forepart of the body; so that the greater part, if not the whole of the liquid contents of the vacuole, must have been ejected behind. The re-expansion of the vacuole takes place very slowly, and it could not be determined whether liquid was directly drawn in from without. Coloured liquids were never observed to enter the vacuole.

PHYSIOLOGICAL ACTION OF COPPER. — For some years past the majority of medical men have no longer considered salts of copper as true poisons, their innocuousness being partly due to the fact that when they are taken in any considerable quantity, they cannot be kept in the stomach, but produce vomiting. It remained to ascertain whether, in animals incapable of vomiting, salts of copper would act as poison. At a recent meeting of the Société de Biologie, M. Gallipe described some experiments on the subject. He had given several rabbits copper with their food. One of these animals received daily, for six months, two grammes of acetate of copper. At the end of this period, the rabbit showed considerable fattening. Its liver weighed 70 grammes, and contained 13 centigrammes of copper. Further, this rabbit was eaten by the experimenters, who were no way incommoded thereby. This is one fact more (says *La Nature*) in favour of the so-called rehabilitation of copper.

LOCALISATION OF ARSENIC IN THE BRAIN.—Experiments have recently been made on guinea pigs by M. De Poncy and Livon (*Comptes Rendus*), with reference to the localisation of arsenic in the brain, when arsenious acid was given in small doses daily with the food. They found that phosphoric acid increased considerably in the urine, and it can only have come (the authors point out) from an elimination by substitution, not from a pathological state of the animal, for in cerebral affections, rather a diminution than an increase of phosphoric acid in the urine has been observed. The arsenic, then, seems to replace the phosphorus of phosphoglyceric acid in lecithine, producing arsenioglyceric acid. The authors are seeking to isolate this new base.

NOTES

PROF. CHRYSTAL of St. Andrews (formerly of Peterhouse, Cambridge) has been appointed to the Chair of Mathematics in Edinburgh University. He was Second Wrangler and Second Smith's Prizeman in 1875, and is already known to science by his experimental researches on Ohm's Law (made in the Cavendish Laboratory) and by the very excellent article "Electricity" in the new edition of the *Encyclopædia Britannica*. Among the eleven candidates for the chair there were four Senior Wranglers. Thus the Chair of Mathematics in St. Andrews is now vacant; and it has just been announced that Prof. Blackburn has requested the University Court of Glasgow to sanction his retirement from the Chair of Mathematics there. As Prof. Fuller of Aberdeen resigned last year only, the whole of the Mathematical Chairs in Scotland have been vacant within one year.

AT the half-yearly general meeting of the Scottish Meteorological Society, held on Monday, July 21, papers were read on "The Cold Weather since November, compared with Periods of Protracted Cold in Scotland from 1764," by Alexander Buchan; on "The Great Plague of London in Relation to Weather," by Dr. Arthur Mitchell; and on "Ground Swells observed in Scotland since 1868," by Alexander Buchan. With reference to the proposal of General Myer to publish maps exhibiting the simultaneous monthly means in meteorology of the whole of the northern hemisphere, intimated in NATURE, vol. xx. p. 275, the Scottish Meteorologists state, in their Report to the meeting, their conviction "that this truly cosmopolitan work, which the United States alone are in a position to undertake, thanks to the enterprise and liberality of their Government, will bring before us, month by month, the general circulation of the earth's atmosphere, and raise at least, if not satisfy, many inquiries lying at the very root of meteorology, and intimately affecting those atmospheric changes which meteorologists hitherto have been recording."

WE have already referred to the valuable "Bibliographical Contributions" issued by the library of Harvard University and edited by Mr. Justin Winsor, the librarian. One of the most scientifically important of these is a list of apparatus available for scientific researches involving accurate measurements, prepared by means of answers to a circular sent out by Professors Wolcott Gibbs, E. C. Pickering, and Trowbridge, of Harvard. This circular speaks of the cost of the apparatus required for exact quantitative determinations in the various branches of

physics, as always having been a serious obstacle to the prosecution of investigations requiring a high degree of precision. It asks, therefore, from the various institutions addressed, a list of such apparatus of this kind as they possess, and which they are willing to place, under certain restrictions, at the disposal of any properly qualified persons for the purpose of investigation. The principal scientific institutions of the State have responded, and the lists they give convey a highly favourable idea of the completeness and high quality of the apparatus of precision with which American laboratories are furnished. Among the institutions thus prepared to place their equipments at the service of science are the United States Coast Survey, the Academy of Arts and Sciences, the various scientific departments of Harvard University, the Stevens Institute of Technology, Massachusetts Institute of Technology, Columbia College, New York, and the Johns Hopkins University, which, though the youngest of these institutions, has an admirably complete scientific equipment. Mr. Winsor is to be congratulated on the wide extension he has given to the significance of the term bibliography, and on the service he is doing science in the United States.

FROM the *Chemical News* we learn that a newly-discovered metal, Norwegium, has been detected and isolated by Dr. Tellef Dahll in a sample of copper-nickel from Kragerö, in Skjærgaarden. The colour of the pure metal is white, with a slight brownish cast. When polished it has a perfectly metallic lustre, but after a time it becomes covered with a thin film of oxide. It can be flattened out in an agate mortar, and in hardness it resembles copper. The melting-point is 350° C., and the specific gravity 9·441. Its equivalent appears to be 145·9. Only one oxide, NgO, has been obtained. With sulphuretted hydrogen it gives a brown sulphide, even in strongly acid hydrochloric solutions, which redissolves in ammonium sulphide. With a slight addition of potassium ferrocyanide it gives a brown, but with larger proportions a green precipitate. The sulphuric solution is turned brown on the addition of zinc, and the metal is deposited in a pulverulent state. The solutions of this metal are blue, but become greenish on dilution.

THE cranium of Descartes is often adduced as an exception to the general rule that a great mind requires a large brain. This statement seems to have rested on no exact measurement, and Dr. Le Bon resolved recently to test its accuracy. The result is that he finds the cubic capacity of Descartes' skull to be 1,700 centimetres, or 150 centimetres above the mean of Parisian crania of the present time. At the same time Dr. Bordier has recently found the average capacity of the skulls of thirty-six guillotined murderers to be 1,547·91 c.c., the largest reaching the high figure of 2,076 c.c.

THE Paris International Exhibition of Sciences applied to Industry will be opened to-day. It is divided into eleven groups. The first group contains prehistoric subjects, anthropology, sociology, and education. The eight following groups are respectively applications of physics, of chemistry, of mechanics, mechanics applied to locomotion, application of the natural sciences, mathematical sciences, the applications of geology, books, and manuscripts. The tenth group will contain (1) The artificial reproduction of a glacier with an interior grotto, which will show the several geological strata containing characteristic fossils. (2) The reproduction on a large scale of a civilised house of the nineteenth century, a hut of savages, and a prehistoric habitation. (3) A map of Europe in the tertiary period executed in relief. (4) A dioramatic view of the actual site of Paris during that period. (5) Another dioramatic view just before the time when man made his first appearance on the earth. Group 11 will be devoted to a retrospective exhibition of objects belonging to art and industry. The most notable innovation will be the creation of a commission of scientific inquiry to obtain information from exhibitors, which will be published with a commentary from the commission. The commission of patronage is composed of MM. Carnot, Dr. Henry Lionville, Henry Martin, Charles Blanc, &c. The works are progressing with great activity, and are lighted by the electric light on the Jablochkoff system, which will illuminate the Exhibition at night.

WE are requested to state that at the Sheffield meeting of the British Association there will be an important exhibition of scientific apparatus and specimens, both in the temporary museum and at one of the *soirées*. Inventors and others who may have objects of interest to exhibit are desired to at once communicate with the local secretaries, Sheffield, as this will be an unusually favourable opportunity for bringing their discoveries before the scientific world.

AT the recent meeting, already referred to by us, of ladies and gentlemen interested in Japanese art, literature, folk-lore, &c., at the rooms of the Royal Asiatic Society, a committee was appointed to consider the best mode of giving effect to that object in communication with the Council of the Royal Asiatic Society. Among the Committee are—Sir Rutherford Alcock, K.C.B., Sir Charles Wentworth Dilke, Bart., M.P., Prof. Robert K. Douglas, Major Gen. A. Lane Fox, F.R.S., E. J. Reed, C.B., M.P., F.R.S., E. B. Tylor, LL.D., F.R.S. At a meeting of this Committee on the 11th inst. it was resolved that for the objects in view a Society should be formed, to be called the "Nipon (Japan) Institute," to consist of members subscribing a sum of 10*s.* per annum, and that the permission of the Council of the Royal Asiatic Society be asked to allow such Society to hold meetings at their rooms, 22, Albemarle Street. It was also resolved that a Committee be appointed to act, with Mr. Pfoundes as Secretary, in the organisation of such Society, and to conduct the necessary correspondence. On this Committee, besides others, are those whose names are given above. It is proposed that the institution shall consist of a Central Institution; a President; Council; General Committee; Councils of Division, *e.g.*, Antiquities, Art, Anthropology, Folk-lore, Geography, History, Language, Literature, &c., and Committees of Sections; a Chief Branch in Tokio, Japan; Branches in Japan, China, India, Australia and other Colonies, United States and other parts of America, Continent of Europe, Provincial Towns of Great Britain, &c.; in Correspondence with Central Institution; Corresponding Members where no branches exist. The Society is to encourage and reply to inquiry; to solicit literary and scientific ladies and gentlemen to suggest subjects for inquiry and collection of material; to arrange lectures, *soirées*, *conversaziones*, exhibitions, social reunions, and parties to view collections, &c.; and otherwise keep alive the public interest in Japanese topics, &c.

THE "Naturforschende Gesellschaft" of Halle will celebrate the 100th anniversary of its foundation on the 30th instant.

THE death, on July 5, is announced of Dr. Reiff, of Tübingen, formerly Professor of Philosophy at the University of that city.

A NEW natural history museum, formerly the private collection of Dr. L. W. Schaufuss, has just been opened to the public at Blasewitz, near Dresden. Dr. Schaufuss has for many years been in close personal relations with the Archduke Ludwig Salvator, of Austria, well known by his scientific writings and travels, and the new museum therefore bears the name of its founder's august friend and patron. Besides numerous natural history objects it also contains others of anthropological and ethnological interest.

A CORRESPONDENT asks if there is any flora of Cape Colony published? and if there is any book which would be useful in the practical study of the Cape flora? In reply we may state that three volumes have been published of Harvey and Sonder's "*Flora Capensis*" (Lovell Reeve). We understand Mr. Dyer

is engaged upon a continuation of it, the fourth volume being now in progress. For a general review of the flora see Harvey's "Genera of South African Plants," edited by Hooker (Reeve); Harvey's "*Thesaurus Capensis*" may sometimes be procured secondhand.

A LARGE number of mammalian bones of the diluvian period have lately been obtained from the bone-cave of Vypustek, Moravia (Prof. K. Th. Liebe, *Proceed.* Imp. Acad. Vienna, May 23, 1879), and sent to the Imperial Museum at Vienna. The comparison of these remains with those from the Thuringian caves is important, especially with those from the cave of Lindenthal near Gera, which led Liebe and Nehring to the interesting conclusion that all this region was an extensive barren steppe, without any forest vegetation, at the beginning of the Second Diluvial Period. In the cave of Vypustek are found—*Lynx vulgaris, Felis catus, Canis spelæus, C. familiaris, Vulpes vulgaris, V. lagopus, Gulo borealis, Martes abietinus, Fœtorius putorius, F. erminea, Vesperugo serotinus, Arvicola amphibius, A.*sp., *Lepus variabilis* (*timidus ?*), *Cricetus frumentarius, Myoxus glis*, and *Sciurus vulgaris*. Besides these seventeen species, von Hochstetter found remains of *Elephas primigenius, Rhinoceros tichorhinus, Equus fossilis, Bos priscus, Cervus tarandus, C. elaphus, C. capreolus, C. euryceros* (?), *Capra ibex, Ursus spelæus, Felis spelæa*, and *Hyæna spelæa*; the number of species found in the Vypustek Cave being therefore twenty-nine. The evidence proves that this cave was a den of beasts of prey, long tenanted by families of hyenas and bears, and occasionally visited by lions, lynxes, and wolves; while many side galleries, some opening to day, gave shelter to martens, weasels, and other small carnivores. Some few animals may have been carried into the cave after death by streams and floods; but by far the greater part of the remains are those of tenants of the cave, or of their prey brought in for food. The fauna of this cave indeed bears a decidedly sylvestran character; and it may be admitted that its environs were covered with woods, and had a forest climate, at the time when northern and middle Germany had the features and climate of a steppe. Hence too the mountains and hills of South Bohemia and Moravia may be supposed to have been the centre from which forests advanced gradually in every direction over the great Diluvial Steppe of Europe north of the Alpine chain. Further explorations, to be conducted by the Prehistoric Commission of the Imperial Academy of Vienna, may lead to further interesting facts as to the relative depth and succession of the animal remains in this cave.

GREAT damage to agriculture has been done by swarms of grasshoppers in Hungary, in the Szathmar Comitat. An area of some 600 Hungarian "Joch" is entirely devastated. The local authorities have been compelled to apply to Budapest for military assistance, besides availing themselves of that of the inhabitants of numerous villages in the districts affected by the plague.

ON July 1 a monthly serial, entitled *Der Phonograph*, appeared at Vienna, edited by Wilhelm Stockinger, and having for its object the cultivation and propagation of Faulmann's "phonography."

IN this month's number of the *Mineralogical Magazine* is the history of a remarkable gem, called the "Maxwell-Stuart" topaz, which is undoubtedly the largest cut precious stone known. Its weight is 1,475·9 grains, or 368 carats 3·9 grains; specific gravity, 3·5685. It is perfectly white and very brilliant. It was brought from Ceylon many years ago, and has been for a considerable time, in an uncut state, in the possession of Mr. Maxwell-Stuart, a collector of gems, after whom it takes its name. An idea of its size may be formed by stating that the table is 2½ inches in length. It was cut and polished in London, under the supervision of Mr. Bryce-Wright, the present owner, the operations occupying twenty-eight days.

MR. MORRIS, the well-known botanist in Ceylon, whose endeavours to find a remedy for the disastrous coffee-leaf disease we have before referred to, has established the fact that very favourable results may be obtained from the application by hand of a mixture composed of three parts of lime and one of sulphur.

THE officers of the French Balloon Committee tried several ascents last week, in order to determine the visibility of terrestrial objects at various altitudes.

AT a recent meeting of the French Physical Society M. Bouty described the action of heat on metallised thermometers. The contraction produced at the moment of deposit of the metal is entirely compensated by the difference of the dilatations of the glass and the metallic envelope, at a temperature which is higher the greater the contraction, and the smaller the difference of the dilatations, but independent of the thickness of the deposit. Above this critical temperature traction takes the place of pressure on the bulb; ruptures presently occur at the surface of contact, and the result is permanent deformations, which produce a new displacement of zero. This latter effect is never produced when the critical temperature is not exceeded. A metallised thermometer may be used to measure temperatures, if it have been compared with a typical thermometer, from which it does not differ sensibly unless the metallic deposit be of considerable thickness. When sulphate of copper is electrolysed between two very sensitive thermometers, coated with copper superficially, the thermometer attached to the positive pole is found to be at a temperature superior, the negative thermometer at a temperature inferior, to that of the surrounding liquid. The same phenomenon is observed in electrolysing sulphate of zinc between two thermometers covered with zinc. M. Bouty recalled the fact that when two plates of zinc or of copper are kept at different temperatures in the corresponding sulphate, a current arises, and the warmer metal is the positive pole. There is between the production of these currents and the phenomena studied by M. Bouty a relation of reversibility similar to that which connects Peltier's phenomenon and ordinary thermo-electric currents.

THE electro-magnetic rotation of the plane of polarisation of light in gases has recently been proved and studied variously by Kundt and Röntgen, Bichat and H. Becquerel. The last-named observer, by a superior method, measured the phenomenon especially in ordinary coal gas, while the others demonstrated the rotation in sulphide of carbon vapour, gaseous sulphurous acid, and sulphuretted hydrogen. In a paper to the Vienna Academy, Prof. Lippich, of Prague, describes additional experiments on the subject. He aimed especially at perfecting the optical part of the apparatus, and attained remarkable accuracy. He succeeded in demonstrating the rotation *in air*, using a large coil 0·5 metres long, with 365 m. length of copper wire (nearly 3 mm. thick) in twelve layers. The current was from sixty average Bunsen elements, combined in a battery of thirty double elements. The light-ray was simply sent through the hollow part of the coil. Under these circumstances an unmistakable electro-magnetic rotation was observed, and it was in the direction of the current coursing round the air. The angle of rotation could not have been far from 6 to 10 seconds of arc. (An exact determination was not possible, owing to the provisional arrangement of the optical apparatus.)

THE last number of the *Journal* of the Society of Arts contains two elaborate papers by Mr. A. T. Atchison and Mr. W. H. Penning, giving suggestions for dividing England and Wales into watershed districts, with reference to the National Water Supply.

THE *Sanitary Record* is now appearing in an enlarged form as a monthly, instead of a weekly as hitherto.

THE additions to the Zoological Society's Gardens during the past week include a Lesser White-nosed Monkey (*Cercopithecus petaurista*) from West Africa, presented by Mr. Robt. F. Clothier; two Ring-tailed Lemurs (*Lemur catta*) from Madagascar, presented by Mr. Hugh McCubbin; a European Bearded Vulture (*Gypaetus barbatus*) from Southern Spain, presented by Lord Lilford, F.Z.S.; three Globose Curassows (*Crax globicera*) from Central America, presented by Major F. Hime; a Lesser Sulphur-crested Cockatoo (*Cacatua tenuirostris*) from Moluccas, presented by Miss Langley; a White-tailed Gnu (*Catoblepas gnu*) from South Africa, two Mule Deer (*Cervus macrotis*) from North America, a Common Ocelot (*Felis pardalis*), a Red and Yellow Macaw (*Ara chloroptera*) from South America, deposited; a Funereal Cockatoo (*Calyptorhynchus funereus*) from New South Wales, four Common Crowned Pigeons (*Goura coronata*) from New Guinea, two Yellow-bellied Parrakeets (*Platycercus flaviventris*) from Tasmania, an American Kestrel (*Tinnunculus sparverius*) from South America, a Smooth Snake (*Coronella lævis*) from Hampshire, purchased.

ON TWO METEORS OBSERVED IN SWEDEN IN 1877 [1]

THE first meteor was observed over a great part of the middle of Sweden from Stockholm, in the east, to Charlottenberg (and Christiania), in the west, and from the neighbourhood of Åreskutan, in the north, to Jönköping, in the south. Accounts of the phenomenon by forty-seven different observers are given. By a comparison of a number of those observations it appears that the meteor was seen nearly simultaneously over the whole of the area where it was visible, on March 18, at 7h. 52·5m. P.M. Greenwich mean time. The phenomenon lasted only a few seconds.

When lines, showing the direction in which the meteor was seen from every separate point of observation to sink under the horizon or in which the last explosion took place, are drawn on the map, most of them meet on the Lake Vener, in the region of Vermlands Näs. The terminal point of the meteor's path was thus clearly situated above this region. Observations from Stockholm, that the meteor disappeared about half way between the moon and the horizon, and from Örebro that it split into fragments by the side of the moon, show that the last explosion took place at a height of 37 to 38 kilometres. Observations from Carlstad and Edsvalla, that the meteor passed through the zenith, and from Mora, that its path was vertical, indicate a projection of its path over Mora and Carlstad, to Vermlands Näs. At first its inclination appears to have been only about 30°, but afterwards it became considerably greater. Besides the final explosion there were three other points of the meteor's path at which it threw out sparks, the first at a very considerable height—*over 200 kilometres*, the second at a height of 100 to 150 kilometres. These figures, for which, however, no great degree of accuracy can be claimed, are deduced from an observation made in the neighbourhood of Örebro. That the continuation of the meteor's path could not be observed from this point was probably caused by the masses of dense cloud which the meteor heaped before it in its path, and which, in the neighbourhood of the place where it fell, almost completely concealed it from view.

As is commonly the case with meteor detonations in general, the sound was propagated with excessive irregularity, violent explosions having been heard in some places, while in others close by the whole phenomenon appeared to proceed without sound.

The circumstance that in the region of Vermlands Näs, at Edsvalla, Carlstad, Kinnekulle, and other places over which the meteor sprang asunder for the last time, no proper fireball was visible, but only a thrice-repeated lightning-like flash, shows that here, too, a part of the meteor's light was intercepted by the dense, cloudy masses which the meteor drove before it. A remarkable observation was made at Skinnskatteberg. There the strongly-luminous meteor projected on the snow-covered ground four or five bands of light with dark intervals, "without there being any object between the meteor and the earth to cast a shadow," the shadow in this case having probably been caused by fragments of cloud in the neighbourhood of the meteor.

[1] By Prof. Nordenskjöld. Abstract of two papers in *Trans.* of the Geological Society of Stockholm, 1878, Nos. 45, 46, and 47.

The diameter of the meteor, as calculated from a number of observations of apparent size, varied from 200 to 2,500 metres. Prof. Nordenskjöld considers it probable that the Vener meteor, in its path through the atmosphere, formed a luminous ball of 400 to 500 metres' diameter.

When the above-described phenomenon took place, the ground in the middle and north of Sweden was still covered with snow, a circumstance favourable for ascertaining whether any solid particles fell from the meteor in question in the form of meteoric dust to the surface of the earth. Prof. Nordenskjöld requested a student, Herr Svenonius, to proceed to the supposed place of fall, and to endeavour, both by his own researches and by inquiries of persons resident in the region, to discover any remains of the meteor. He travelled several times across the region, and employed a large number of people in searching on the ice on Lake Vener. The result was negative, with the exception that Herr Svenonius found on Lake Vener small quantities of a black or dark grey dust, of doubtful origin, which under the microscope appeared to consist of—

1. Small aggregates of cells derived from higher plants and isolated or coupled plant-cells.
2. A black colloid substance, which formed the main mass of the dust.
3. Inorganic particles of dust, which were *isotropical*, and could thereby be easily distinguished from grains of sand, which entered very sparingly into the mixture. The dust scarcely contained any particles that were capable of being attracted by the magnet, whereby it differed completely from the dust collected on the polar ice during the Swedish expedition of 1872-73. From the small quantity of material that could be employed for analysis, no complete chemical examination of the inorganic constituents could be carried out. The principal constituents were silica, 38 per cent., oxide of iron, 34 per cent., alumina, 8 per cent. No trace of cobalt, nickel, or phosphorus could be discovered.

The dust was found in small quantity on the borders of the small pools, which, under the influence of the spring rise of temperature, were formed everywhere on the ice of Lake Vener.

It is probable that this meteor mainly consisted partly of gaseous substances, partly of carbon, so finely divided that it was completely burned during the short path of the meteor in the atmosphere of our globe.

The second meteor was seen on April 29 at 8.37 P.M. Greenwich mean time, over the greater part of Sweden, from a point lying a little to the south-east of Gothenburg to Vittangi in the extreme north. It was also seen over a great part of Finland, and at St. Petersburg and Dorpat. Accounts from no fewer than seventy-three different places are given. The meteor had, when first observed, the appearance of a large star. Its size increased, however, at first slowly, afterwards rapidly, so that it at length gave out a light so bright that the country over which it passed was lighted up as if it had been full day. The light increased in brightness until the meteor exploded about half way between Luleå and Piteå at a height of 35 kilometres. The time that elapsed between the first appearance of the meteor and its explosion did not exceed a minute and a half. The phenomenon, however, did not come to an end then. A part of the meteor appears, after the explosion, to have continued its course, and perhaps may have passed out of the atmosphere. Besides the usual line of sparks which generally marks the path of a meteor for some moments, there occurred in this case along a considerable part of the path a splendid light phenomenon of a red colour, *which, however, was only observed in regions far removed from the place of explosion*. This red appearance lasted from fifteen to thirty minutes. After it ceased the path of the meteor was still marked in the heavens for a long time (upwards of an hour) as a light band of cloud, which first assumed a zigzag form and then gradually disappeared. The whole phenomenon accordingly lasted nearly two hours, and it is probable *that the meteor, or parts of it, both when it first appeared as a star and after the red light ceased, shone not with its own light but with light reflected from the sun*.

The statements as to the time during which the *fire-ball itself* was luminous in the atmosphere differ, varying from some few to ninety seconds. The latter, however, is the only one which has reference to the whole of the time during which the meteor was luminous from its first appearance as a large star to its explosion.

in the region of Luleå. The red light was visible at different places for periods varying from ten to thirty minutes, the light streak of cloud from some minutes to seventy-five, the whole phenomenon being visible from ten to 105 minutes.

At places nearest to the locality of explosion and at some others there was seen only the intensely luminous fire-ball, not the red after-light, probably in part owing to the sky being cloudy, and in part also for the same reason as that which caused the dark central field in the case of the Ställdalen meteor.

The observations reported correspond so closely with the figures calculated on the supposition that the explosion took place *half way between Luleå and Nederkalix at a height of* 35 *kilometres above the surface of the earth*, that this point of the meteor's path may be considered as determined with considerable accuracy.

All observers agree in this, that the red pillar of fire which immediately after the explosion was seen at Upsala, Stockholm, Fredrikshamn, St. Petersburg, &c., had at first the same direction as the meteor's spark-bestrewn path, but that the position of the fire-pillar towards the close of the phenomenon underwent change by its spreading out to a height in the atmosphere which in the north of the Gulf of Bothnia was about three times as great as that of the fire-ball proper.

The tangent of the meteor's path at the place of fall had an inclination to the horizon of about 25°. The radiation point was situated somewhere in the constellation Orion. The meteor appears to have been first seen at a height at which it was beyond the earth's shadow, and illuminated by the sun. At first it had the appearance of a bright star, but afterwards increased rapidly in diameter till its apparent size was equal to that of the sun or moon. From a comparison of numerous observation it appears that the meteor's luminous nucleus had a diameter of 1,000 metres.

The Luleå meteor is interesting for the splendid light-phenomenon visible after its explosion, and particularly for the long time it remained in the atmosphere without much change of place.

This light began immediately before the meteor exploded in the region of Luleå, but it could not have been caused by combustible substances thrown off in consequence of the explosion, as in that case the red light ought to have spread itself from the place of explosion about equally in all directions, and afterwards have sunk down rapidly and gone out. Instead, this light was extended in the direction of the meteor's path, and it remained in the sky for more than an hour. An approximate idea of its size and height in the atmosphere is given by observations at Upsala and Fredrikshamn:—

	Breadth of the red luminous pillar.	Approximate height of the point.
Upsala (2)	6 kilom.	125 kilom.
Fredrikshamn ...	12 ,,	150 ,,

The appearance of this light varied much. At some places it resembled a pillar of equal breadth ("like a beam"), at others it appeared as a red spot, from which a pillar of the same colour descended to the horizon but disappeared sooner; at others, again, luminous rings were observed. After the light itself disappeared, its position in the sky was marked for a long time by numbers of "wool-like" clouds.

Several observers remark that the red fire-pillar in question, during the time that it remained visible in the sky, slowly assumed a more vertical position, and then took the form of a 7 or a reversed S.

The Luleå meteor besides, like most other meteors, left behind it for some moments a white luminous streak of fire in that part of the sky through which it passed. This streak of fire clearly arose from constituent parts of the fireball proper which had been loosened by the resistance of the air, and remained behind.

The red light, on the other hand, appears to have had a different origin. It could not have consisted of small particles left behind in the uppermost strata of the atmosphere, for they would speedily have fallen down. The light rather appears to have originated from new combustible or luminous material which followed the nucleus of the meteor, and for the space of half an hour entered the atmosphere at nearly the same place. The Luleå meteor was thus a true cometoid.

It appears that the attraction of the earth and the retardation caused by the resistance of the air gave the path of the dust, causing the red light, a more parabolic form than that of the meteor's nucleus, for a number of observers state that the red pillar gradually raised itself from the slanting position of the path of the meteor towards the vertical line. The direction of the meteor's train, as in the case of true comets, did not lie quite in the path of the meteor. The foot of the luminous pillar was observed above Avasaxa at a height of about 100 kilometres when the nucleus exploded north of Luleå. After the disappearance of the red light there remained white and woolly clouds, resembling light clouds illuminated by the sun. These may have arisen from parts of the meteor which were directly illuminated by the sun, and thus became visible when the stronger light, caused by direct combustion, ceased. On April 29, in the latitude of Avasaxa, bodies at a greater height from the surface of the earth than 76 kilometres are beyond the shadow of the earth even at midnight.

The meteor's light was at first white, then for a long time of the same shade of red as the dawn, and near the close of the phenomenon again white. The light probably arose from the combustion of carbon and carburetted hydrogen, the products of combustion, steam, carbonic acid, &c., absorbing part of the rays of light, and giving the nucleus a reddish tinge. Towards the close the gaseous envelope was dispersed, and the red colour ceased a long while before the meteor finally disappeared. Search was made for any meteorites or meteoric dust that might have fallen, but none were found, although stones were seen to fall to the ground "like rain" by two Lapp girls near Jockmock, and a Lapp reindeer-herd on the mountain Sarvikobbo saw the "stone-swarm" in question disappear in the forest *below* him.

SCIENTIFIC SERIALS

Annalen der Physik und Chemie, No. 6.—In view of the considerable discrepancy between observation and theory with regard to the propagation of electricity, Herr Lorenz has been led to make fresh experiments (here described). In one method the telephone was used; the other was a modification of Feddersen's jar-discharge method. Herr Lorenz shows that, in the case of iron telegraph lines, the magnetism of the iron must be considered. The electro-dynamic constant of unit length of an overland telegraph wire is expressed by $C = 2 \log. \frac{2h}{a} + 2\pi k$, where h denotes the height above the ground, a the radius of the wire, and k the function of magnetisation. For unmagnetic wires, the latter member falls away. Applying the formula to Fizeau and Gonnelle's experiments, and putting the function of magnetisation of the iron wire = 10, we get the velocity 126000 km., while that observed was 101710 km. The difference is much less than by the ordinary reckoning, and may be attributed, the author thinks, to faults of insulation.—Studying the generation of the currents of a Gramme machine with regard to time and resistance, Herr Herwig finds, *inter alia*, that at the commencement a greater manifestation of force is obtained with greater resistances; but in later stages of development of the current, the force increases more for smaller resistances. The slow development of current with great resistances is shown by the fact that with 13·4 Siemens' units, the full force possible was not reached in four seconds.—Prof. Colley concludes from experiment, that the "polarisation of electrodes" in electrolytes is not to be attributed to dielectric polarisation of the latter, but deserves the name just given. It is not denied, however, that the dielectric polarisation may exist, being completely masked by the other.—Herr Settegaast makes some contributions to quantitative spectral analysis; his paper treating (1) of distribution of a base between chromic acid and other acids; (2) of quantitative mode of determination of nitric acid, and (3) of determination of phosphoric acid.—Among the remaining subjects handled, we note the angle of polarisation of fuchsin (Glan), application of the method of dimensions to proof of physical propositions (Neesen), and the heat-conduction of liquids with reference to currents arising from differences of temperature (Oberbeck).

THE *Quarterly Journal of Microscopical Science*, July, contains:—Notes on some of the reticularian rhizopoda of the *Challenger* expedition, by H. B. Brady, F.R.S., with a plate. In this second memoir several new and most interesting forms are described and figured. The author mentions that he has failed to detect in fresh specimens of *Dactylopora eruca*, P. & J., the structures figured by M. Munier-Chalmas, which figures happen to be reproduced in this number of the Journal, as part of the minutes of the Dublin Microscopical Club.—On the morphology of the vertebrate olfactory organ, by A. M. Marshall, M.A., with two plates.—On the brain of *Blatta orientalis*, by E. T. Newton, with two plates.—On the microphytes which have been found in the blood and their relation to disease, by Dr. T. R. Lewis, with

a plate.—Observations on the glandular epithelium and division of nuclei in the skin of the newt, by Dr. Klein, with a plate.—On the early development of the Lacertilia, with observations on the nature and relations of the primitive streak, by F. M. Balfour, M.A., with a plate.—On certain points in the anatomy of *Peripatus capensis*, by F. M. Balfour, M.A.—Notes and Memoranda.—Proceedings of the Dublin Microscopical club from November 21, 1878, to March 20, 1879.

THE *Journal of Anatomy and Physiology, Normal and Pathological*, July, contains:—On supernumerary nipples and mammæ, with an account of 65 instances observed by Dr. J. M. Bruce, with a plate.—On the origin and composition of the bodies found in compound ganglia, by Dr. G. T. Beatson.—On the physiology of the Turkish bath, being an inquiry into the effects of hot dry air upon man, by Dr. W. J. Fleming.—On the form and structure of the teeth of *Mesoplodon layardii* and *M. sowerbyii*, by Prof. Dr. Turner.—On the element of symbolic correlation in expression, by Prof. Dr. Cleland.—On an intra-thoracic lymphoid tumour, by Dr. R. H. Clay.—On inequality in length of the lower limbs, by Dr. J. G. Garson.—On a large subarachnoid cyst involving the greater part of the parietal lobe of the brain, by Dr. D. J. Cunningham.—On the process of healing, by Dr. D. J. Hamilton, with a plate.—On the dentition of *Bettongia penicillatus*, Gray, by George Leslie.—On a new theory of contraction of striated muscle, and demonstration of the composition of the broad dark bands, by Dr. D. Newman, with two plates.—Note of a case of articulation between two ribs, by Dr. J. H. Scott, with a note by Prof. Dr. Turner.—Additional note on the organ of Bojanus, by M. M. Hartog, M.A.—On a two-headed sartorius, by G. S. Brock.—Note on ethidene, by Prof. Dr. M'Kendrick.—Notice of Kölliker's "Developmental History of Men and the Higher Animals," by F. M. Balfour.

Zeitschrift für wissenschaftliche Zoologie, Bd. xxxii. Heft iii., contains:—Studies among the sponges, by Prof. Elias Metschnikoff, of Odessa, containing notes on the development of *Halisarca dujardinii*, on the anatomy of Ascetta, on the history of development in the calcareous sponges, on the inception of nourishment in sponges, and concluding with some general remarks on the group. Four folding plates illustrate this memoir.—On the power possessed by different mammals of holding fast to and moving upwards by means of atmospheric pressure on smooth and more or less perpendicular surfaces, by Dr. O. Mohnike.—Contributions to our knowledge of the organs of generation in the free living copepoda, by Dr. A. Gruber, with five plates.—Researches on the minute structure of the intestinal canal in *Emys europæa*, by Dr. J. Machate, with a plate.—On a new species of infusorian (*Tintinnus semiciliatus*), by Dr. V. Sterki, with figures.—On the final alterations in Meckel's cartilage, by Dr. B. Baumüller, with two plates.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, July 14.—M. Daubrée in the chair.—The following papers were read:—Addition to my memoir on the principle of least action, by M. Serret.—On the direct combination of cyanogen with hydrogen and the metals, by M. Berthelot. Cyanogen and hydrogen, pure and dry, mixed in equal volumes, and sent through a narrow glass tube heated to 500° to 550°, give some sign of combination; but the reaction is more complete when the mixture is heated several hours to the same temperature in a sealed tube of hard glass; this is afterwards opened over mercury. The union of cyanogen with some metals was found also to be merely a question of time and temperature. The substances were heated together in a sealed tube. Silver and mercury did not combine with cyanogen at any temperature. The analogies of cyanogen with the halogen substances are extended in this inquiry, beyond formulæ, to methods of direct synthesis.—On the organo-metallic radicals of tin: stannbutyls and stannamyls, by MM. Cahours and Demarçay.—On an application of the theory of elliptic functions, by M. Picard.—Researches on the effects of the rheostatic machine, by M. Planté. Using a machine of 80 condensers charged by his secondary battery of 800 couples, he obtains noisy sparks more than 0·12 m. long, and if they are produced above an insulating surface sprinkled with flowers of sulphur, they may even attain 0·15 m., and leave a sinuous furrow. When short of their maximum length they often form closed branches like *anastomoses*; also, on the sprinkled surface, *arborescences*, which appear after removing the excess of sulphur by a few light taps. This, M. Planté thinks, may explain the plant-like impressions sometimes found on the bodies of persons struck by lightning. But little dynamic electricity is required for these and other static effects described (that from 3 or 4 Daniell elements). By associating all the condensers in surface, and adding a small special rotating commutator, static effects of *quantity* are had, different from those of *tension*. By mechanical force of successive sparks M. Planté elevates water.—On the treatment by submersion of vines attacked by phylloxera, by M. Faucon. Some of the insects always survive.—On the phylloxera in the Côte d'Or, by M. Viallane.—On the treatment of anthracnose; observations of M. Puel, by M. Portes. The efficacy of lime is demonstrated.—Observations at Marseilles Observatory, by M. Stephan.—On a definite integral, by M. Callandreau.—On the integration of equations with partial derivatives of orders superior to the first, by M. Pellet.—Minimum of dispersion of prisms; achromatism of two lenses of the same substance, by M. Thollon. Two lenses of the same substance, traversed, the one at the minimum of dispersion, the other at the minimum of deviation, by a luminous beam, may at once deflect and achromatise the light. Hence a system of lenses of the same matter may be made, having one focus and at the same time being achromatic.—On the vapour of bisulphydrate of ammonia, by M. Isambert.—On the dissolution of carbonic oxide in acid protochloride of copper, by M. Hammerl. A thermo-chemical investigation.—On the transformation of tartaric acid into glyceric and pyruvic acids, by M. Bouchardat.—On the isomerism of borneol, by M. De Montgolfier.—On bichlorhydrate of turpentine, by the same.—On some derivatives of indigotine, by M. Giraud.—Comparison of effects of inhalations of chloroform and ether, in anæsthetic and in toxical dose, on the heart and the respiration; applications, by M. Arloing. In the first phase attention should be given both to the heart and the respiration, whether chloroform or ether be used; in the second, the heart must be watched, and especially in the case of chloroform; in the third, the respiration. Chloroform should be preferred to ether, where the operation may be long, as the *denouement* of intoxication by ether is more sudden.—Causes of death from intravenous injection of milk and sugar, by MM. Moutard-Martin and Richet. Death from injection of a great quantity of milk is the result of bulbar anæmia, which produces phenomena of excitation.—On the reproduction of Amblystomas at the Museum of Natural History, by M. Vaillant.—Comparative anatomy of the Hirudineæ; organisation of the *Batracobdella latasti*, C. Vig., by M. Vignier.

THURSDAY, JULY 31, 1879

THE NEW NATURAL HISTORY MUSEUM

NOTWITHSTANDING the delay caused by discussions on the Zulu campaign and the Army Discipline Bill, the Civil Service Estimates must shortly come before the House of Commons, and an opportunity will be given for obtaining from the Government some explanation of the course they propose to adopt with regard to the administration of the New Museum of Natural History. As will be seen by the memorial, of which we gave a copy some weeks ago, the Council of the British Association for the Advancement of Science, in accordance with the resolution adopted by the Association at the Dublin meeting, have strongly urged the pressing importance of this question upon the Government. Naturalists, we believe, are one and all of the same mind on this subject, but owing to the many important political questions of the day, and to the general ignorance of, or we may perhaps say, indifference to, the true wants of science, find it very difficult to get their wishes attended to. Their general opinion upon the British Museum question may, we believe, be shortly stated as follows.

The dominant idea, as we all know, of the Founders of the British Museum was the library. The collections of natural history and antiquities which have been added to it during the past fifty years have always been regarded as entirely subordinate, and not-to-be-too-much-encouraged parts of the general scheme. The executive officer of the whole institution has always been the "principal librarian," trained up in the book department, and having his great aim and object to make that department as perfect as possible. Some years ago, in obedience to pressure from without, an eminent naturalist was made "superintendent" of the four sections of the museum which relate to natural history, namely, zoology, botany, geology, and mineralogy, but care was taken to give him no real power, and his authority, we believe, has remained completely nominal up to the present day. The "superintendent of the natural history departments" has never been allowed to interfere in any way with the important functions of the principal librarian, in whom the administrative power of the whole of the Museum is vested. Now fifty years ago, in the infancy of natural history in this country, such an arrangement as this might have answered very well, but with the gigantic strides that science has made of late years, it is not likely that naturalists will be content to allow the great National Museum of the country to continue to be governed by an individual of no scientific attainments whatever, and to be entirely subordinated to the predominant interests of the Public Library. When the Royal Commission on Science was appointed in 1872, and the question of the British Museum came before it, the grievances of the naturalists found vent, and the systematic injustice with which this department of the Museum had always been treated was fully exposed. After taking full evidence on this subject, the Royal Commission came to the conclusion that the objections raised to the present system of government of the natural history collections were "well founded," and were "unable to discover that the system is attended by any compensating advantages." The Royal Commission recommended consequently that the opportunity should be taken of the proposed removal of these collections into the new building at South Kensington, to separate them at the same time entirely from the control of the trustees and to place them under the rule of a director, who should be responsible to one of the Ministers of State.

It might have been well supposed that such a recommendation, coming as it did from a Royal Commission composed of some of the leading scientific authorities of the country, and backed by the universal opinion of naturalists, would not have been ignored. But such is the apathy displayed by our Government, when questions merely of scientific interest are at stake, that the recommendation appears to have been entirely overlooked. At the fag end of last session the trustees of the British Museum were permitted to pass an act enabling them to move the natural history collections to South Kensington without making any changes whatever in the mode of their administration, and not a single member of the Legislature appears to have raised his voice against this summary mode of dealing with the question.

Unless something can be done to upset the conclusion thus arrived at, it is obvious that the evils so loudly complained of during the stay of the natural history collections in Bloomsbury will accompany them in their migration to South Kensington. The library at Bloomsbury will continue to be regarded as the main business of the fifty trustees, and the natural history at South Kensington will, as of old, be starved in order to feed the wants of the more favoured institution. Besides this, many absurd laws and antiquated regulations exist in the British Museum which it would be highly inexpedient to introduce into a new institution, and which can only be got rid of by a complete change of the ruling powers.

It is said that the trustees of the British Museum, having had the memorial of the British Association pressed upon their attention by the Treasury, are prepared to make certain concessions as regards the management of the New Museum at South Kensington. But in the face of the strong recommendations of the Royal Commission we do not believe that any arrangement of this character will be deemed satisfactory.

In fact, the only hope of good government for the new Museum of Natural History lies in its entire separation from the unnatural foster-sister with which it has been hitherto reared. Every man of science will, we think, agree with the Duke of Devonshire's Commission in considering that natural history has now full claims to a separate maintenance, and will render thanks to the Council of the British Association for their efforts to impress the importance of the recommendations of that Commission upon Her Majesty's Government.

BRAIN AND MIND

The Relations of Brain and Mind. By Henry Calderwood, LL.D., Professor of Moral Philosophy in the University of Edinburgh. (London: Macmillan and Co., 1879.)

THE object of this work, Prof. Calderwood says in his preface, "is to ascertain what theory of mental life is warranted on strictly scientific evidence."

"The order followed is to consider, *first*, the latest

results of anatomical and physiological research as to the structure and functions of the brain; *second*, the facts in human life unaccounted for by anatomical and physiological science, and requiring to be assigned to a higher nature."

In these words our author indicates not merely his method, but the conclusions as to the relations of mind and brain to which his investigations have led him.

The first six chapters deal with the anatomy and physiology of the brain, both human and comparative. In these and also in other parts of the work Prof. Calderwood exhibits an extensive acquaintance with the facts of cerebral anatomy, physiology, and pathology, worthy of any technical neurologist, and which reflects especial credit on an author hitherto identified with purely speculative philosophy.

As the result of his study of the comparative anatomy and physiology of the brain, he reaches the position that the brains most elaborate in convolution are indicative mainly of the most highly developed muscular system. The development of the brain is, however, no test of "intelligence." This, he contends, is most strikingly brought out by a comparison of the brain of man and the ape. "The ape, with a brain modelled like man's, and weighing 15 to 20 oz., shows himself active, powerful, and able to assail any adversary; man, with a brain better developed, and 10 to 15 oz. heavier, is tottering, feeble, and idiotic, unable to defend himself from even a weak assailant. If configuration and structure of brain afford a measure of intelligence, our poor idiotic fellow-man should be so much clearer in intellect and decided in action than the highest specimens of apes. But it is not so" (p. 161).

The comparison here instituted is a very fallacious one. The exact formula for the relationship between brain development and intelligence in different animals has yet to be found. That it is not a mere matter of size is generally admitted. But that the relationship is thorough-going is proved by the very fact here alluded to by Prof. Calderwood, that below a certain standard of development idiocy is the invariable result. The comparison should not be between a microcephalic idiot and a normal ape, but between a normal ape and a microcephalic one. The microcephalic ape would certainly be idiotic.

At the close of his review of the facts of cerebral anatomy and physiology Prof. Calderwood says: "At this stage it seems our only possible conclusion that anatomical and physiological investigation as to brain and nerve, so far as they have yet been carried, afford no explanation of our most ordinary intellectual exercises" (p. 216).

He quotes with approval Prof. Tyndall's words that "the passage from the physics of the brain to the corresponding facts of consciousness is unthinkable," &c. (p. 212); but not content to accept the two as correlated facts insusceptible of further simplification, he endeavours to prove by "personal experience" that mind is altogether distinct from brain, and of a higher and immaterial nature.

"That we discriminate between sensations and perceptions, and consequently form conceptions of things, are facts towards the explanation of which all that is known concerning the action of nerve-fibres and cellular substance contributes nothing" (p. 224). "The known laws of brain action do not provide for this; they imply that the nerve system is not equal to such work" (p. 221).

In his chapter on "Experience as connected with Motor Activity" (Chapter VIII.) we find the following account of the nature of volition:—"What we mean by volition or exercise of will-power is best shown, in the first instance, by marking its contrast with nerve-action. It is not that which moves the muscles, but that which moves the nerve-cells to act upon the muscles. It is not that which moves the limbs, but that which determines that they shall be moved. In its lower and simpler aspect this may be illustrated by reference to sensory activity. A falling stick touches the hand, or a neighbour jostles the elbow. By contact with some external body, an impulse is given to the sensory nerve which is transmitted to the sensory cells. Let us now turn to motor activity. In so far as the originating power *acts upon* the motor apparatus, its action is, in a sense, analogous to that which produces a tactile impression—it operates as an external power, that is, *external* to the apparatus. Or, to take a form of expression more familiar, there comes from an inner sphere, from the region of personal experience, an impulse which acts upon the motor cell, and throws it into activity. That which acts upon the motor cells is as certainly external to the system as is the object which comes into contact with the sensory system. But in the case of voluntary muscular activity, that which operates acts directly on the cell. And what is not reflex, as not being the product of movement of the sensory nerve, must be accounted for by energy from some other quarter, that is, from a sphere external to the nerve system, though within the nature of the person" (p. 247).

Such being the standpoint assumed by Prof. Calderwood in reference to the simplest forms of mental manifestation, it is unnecessary to follow him in his analysis of the higher mental operations.

He advocates *essentially* the so-called "clavier" theory, that the mind is something of a higher nature and distinct from brain, which plays on brain as on a musical instrument. If the brain is diseased, mental manifestations will be limited or inharmonious, but the defect is purely in the instrument, and not in the performer.

Prof. Calderwood admits that the brain is the organ of the mind; that "a pure independence of mind is not known in our history" (p. 314); that defective development of the brain and idiocy invariably go together; that diseases of the brain are associated with mental derangement (Chapter XIII., "Brain Disorders") and deficiencies (Chapter X., "Use of Speech"); that mind has a powerful influence on body, and that mental work implies physiological waste (Chapter XI., "Action and Reaction of Body and Mind"); and yet, notwithstanding the thoroughgoing correlation between mind and brain which these and similar facts demonstrate, he professes by the aid of personal experience to prove the existence of something distinct from and independent of the conditions of its manifestation. This process reminds one very much of an attempt to lift oneself by the hair of the head, or raise the chair on which one sits. Prof. Calderwood cannot divest himself of his brain by personal experience, nor can he give us any evidence of personal experience without brain.

He acknowledges that "however carefully we study consciousness, we do not thereby attain to any knowledge of the nerve system," and that "only by the slow and

laborious methods of anatomical and physiological research has the human race become aware of the physical conditions of sensory impressions and motor activity" (p. 212).

So far, therefore, as personal experience is concerned, Prof. Calderwood might have equally well relied on it for asserting that sensation and voluntary motion are independent of sensory and motor nerve structures, as for his assertion that mental operations are distinct from the action of brain.

That we are in ignorance of the physical processes underlying many special psychical manifestations may be admitted without invalidating the general fact of their correlation, otherwise clearly established. But to make ignorance on the one side the basis of very positive statements on the other, is to say the least extremely rash. We may not know how or under what collocations of nerve cells and nerve structures subjectivity becomes apparent; but for Prof. Calderwood to exclude it in his definition of the properties and modes of activity of nerves and nerve-centres, and then to argue that personal experience demonstrates it to be something beyond and above, is to beg the whole question.

He very ingenuously estimates the true value of such an argument in a passage, in which he says, "the insufficiency of brain and nerve to perform such work *is really involved in the statement of the laws of brain action and the functions identified as belonging to fibres and cells*" (p. 1. 122, ital. ours). It would be more logical to reconsider and amend the definition.

Prof. Calderwood's endeavour to prove by scientific evidence the distinct nature and independence of mind, is to attempt the impossible. The utmost that scientific evidence is able to accomplish is to show that cerebral activity and the facts of consciousness are correlated facts insusceptible of further simplification and incapable of being expressed in terms of the other.

Whether we adopt the hypothesis of a duality or a dual unity, is a question of faith, not of scientific demonstration. Science can only deal with the knowable.

Considering the very decided stand Prof. Calderwood has taken on the dual theory in the light of the latest researches in cerebral physiology and pathology, it was not unreasonable to expect some new contribution towards the elucidation of the vexed question as to how the immaterial mind can act and be reacted on by the material body. As to whether they are attuned on the pre-established harmony principle or otherwise, Prof. Calderwood gives us no information. On the whole, perhaps, he has in this exercised a wise discretion. But whatever theory as to the intimate nature of mind and brain may be adopted, the correlationship between the psychical and the physical must be accepted, not merely in a general sense, but as regards each individual manifestation. Any work will be gladly welcomed, and will do great service, which serves to throw further light on the relations between psychical phenomena and their anatomical and physiological substrata. Prof. Calderwood's work does not help us in this respect:—rather the reverse. While, as regards the facts of brain on the one hand, and the facts of mind on the other, it contains much that is worthy of praise, as regards their relations it is eminently unsatisfactory.

D. FERRIER

SOUTH-INDIAN PALÆOGRAPHY

Elements of South-Indian Palæography from the Fourth to the Seventeenth Century, A.D. By A. C. Burnell. Second Enlarged and Improved Edition. (London: Trübner and Co., 1878.)

A WORK like that before us is one of those which make us feel proud of our Indian civil servants. Dr. Burnell has made a name for himself in a field of research peculiarly his own, and the appearance of a second edition of his important work on South-Indian Palæography is a matter of congratulation for science. Apart from the historical and linguistic value of the numerous inscriptions here copied and explained, the light thrown by their decipherment upon an obscure chapter in the history of writing is so important that I shall make no excuse for confining myself to this side of Dr. Burnell's labours, the more especially as this is the side to which he has himself devoted the larger part of his book.

Two questions are brought before us at its outset—the date of the introduction of writing into India and the origin of the South-Indian alphabets. The two questions, indeed, hang very closely together, and the one cannot be completely decided without the help of the other. The earliest examples of writing yet discovered in India are the edicts of Aṣoka, the Constantine of Buddhism, about 250 B.C. They are written in two different alphabets, and the irregularities they present have been supposed to show that writing was still a recent art. The alphabet of the northern inscriptions, which may be termed the North Aṣoka alphabet, has been proved by Mr. Thomas to have been derived from an Aramaic original, and consequently to have been introduced by Semitic traders from the Persian Gulf. Dr. Burnell claims a similar origin for the South Aṣoka alphabet, as well as for a third alphabet used only in Southern India, and known as the Vaṯṯeḻuttu or Old Tamil. Of this Dr. Burnell holds that it "is apparently not derived from nor the source of the Southern Aṣoka alphabet, though in some respects very near to it."

These opinions of Dr. Burnell have met with a vigorous opponent in Mr. Thomas, who maintains that both the southern alphabets were of Dravidian origin, the Sanskrit alphabet itself being an adaptation of some pre-existing Dravidian one. But it will be difficult to resist the force of Dr. Burnell's arguments based upon the earliest forms of the South Indian characters and their likeness to corresponding characters in the Aramaic alphabets of the fourth and third centuries B.C. As he justly observes: "perhaps the most important proof of the Semitic origin of the two South Indian alphabets is the imperfect system of marking the vowels which is common to them both. They have, like the Semitic alphabets, initial characters for them, but in the middle of words these letters are marked by mere additions to the preceding consonant."

If we once admit with Dr. Burnell that the South Indian alphabets have the same Phœnician origin as most of the other alphabets of the world, we must go further with him and derive them "from an Aramaic character used in Persia or rather in Babylonia." The progress of palæography has made it impossible to derive

them directly from Phœnicia, as Benfey wished to do, or from the Himyaritic characters of Yemen as Lenormant alleges. The traditional belief of the Hindus that their ancient literature was handed down by oral recitation alone is thus confirmed, and a remarkable illustration afforded of the powers of a trained memory. The famous maxim that a literature cannot exist without writing must be given up, and the rigid sceptics who refuse to admit that any historical truth can be extracted from oral tradition lose their most formidable argument.

The earliest material used for writing purposes in India seems to have been the bark of the *bhûrja*, which is usually identified with the birch. It is worth notice that our own word *book* has the same origin as *beech*, and testifies to a similar employment of the bark of the beech-tree among our Teutonic ancestors. It is probable, however, that the characters of our first "books" were cut upon the soft wood or bark of the beech in the form of runes, and not painted as in the case of the birch books of ancient India. Nevertheless we must not forget that Venantius Fortunatus when alluding to the runes in the seventh century speaks of them as being "painted" on tablets of ash.

A. H. SAYCE

OUR BOOK SHELF

Parasites; a Treatise on the Entozoa of Man and Animals, including some Account of the Ectozoa. By T. Spencer Cobbold, M.D., F.R.S., F.L.S. (London: J. and A. Churchill, 1879.)

THERE are several groups of animals which from time immemorial have been more or less generally neglected by zoologists, and which have induced but very few amongst the latter to make a specialty of their investigation. As an instance of comparatively highly developed animals to which this remark applies, we need only point to the whole class of cephalopoda, and among the lower animals the entozoa are certainly a good case in point. Apart from the comparative scantiness of the literature treating of these animals, it has the additional disadvantage, in common with much other zoological literature, of being scattered in the numerous volumes of several hundred different scientific serials. Dr. Cobbold has for a long time been held an eminent authority on helminthology, and, as he states in his preface, many hundreds of correspondents, not having ready access to the works of Rudolphi, Diesing, and Dujardin (three great foreign authorities on the subject), have applied to him for identification of parasites they met with in dissections or otherwise. He therefore pronounces the most justified hope that by the work now published a reasonable limit may be placed upon the number of future applicants. What particularly characterises Dr. Cobbold's work is the thoroughly scientific enthusiasm with which it is written, and which in itself is admirable. We cannot help reproducing the closing sentences of the preface, which will give to our readers a true notion of the spirit to which, according to our view, a scientific work ought to owe its origin:—

"The study of the structure and economy of a humble parasite brings to the investigator no slight insight into the workings of nature. If these workings cannot at all times be pronounced to be 'good and beautiful,' they must at least be characterised as 'true.' The knowledge of the true—especially if that knowledge by its practical applications be calculated to confer substantial benefits upon man and his inferior fellow-creatures—ought to be held in high esteem; but apart from this purely utilitarian view, there remains for the investigator the delight occasioned by the inrush of new scientific ideas. The average mind, being either essentially commercial or ridiculously sentimental, as the case may be, is totally incapable of comprehending the motive power that animates and guides the votary of science. The late Prof. Faraday, a man wholly untinged by the ambitions of wealth and power, once remarked to me that there were no people so difficult to instruct as those who were ignorant of their own ignorance. It is just these very persons who, when placed in high positions of social, political, or professional trust, most powerfully contribute to check a nation's progress. There are too few genuine workers at science in this country. As one of the rank and file I claim only to have honestly contributed my mite. I should like to see a small army of helminthologists rise up and lay siege to the fortresses at present securely held by thousands of death-dealing parasites." None but an honest and true worker will write such sentences as these; every well-meaning man of science must concur with Dr. Cobbold in the ideas he thus forcibly expresses. Upon an array of workers of Dr. Cobbold's stamp a nation may justly look with pride.

Turning now to the book itself we need hardly say that the author has executed the task he set himself in a most praiseworthy manner. Apart from a voluminous contribution of original work, he has consulted an almost interminable list of bibliographies on the various kinds of parasites, a work which in itself involved stupendous labour.

The contents are divided into two large groups, the parasites of man occupying the first division, and those of animals the second. Each division is subdivided into several sections, and thus in the first we have descriptions in one section of Trematoda or flukes, in the other those of Cestoda or tapeworms, in the third those of Nematoda or round- and thread-worms, and in the last those of Acantocephala (thorn-headed worms), Suctoria (leeches), and the parasitic forms of Arachnida, Crustacea, Insecta, and Protozoa. In the second division the parasites of animals are arranged according to the respective places of their hosts in systematic zoology. The parasites of Mammalia are subdivided according to the orders in this class, beginning with Quadrumana and ending with Marsupialia and Cetacea. After this the parasites of birds, reptiles, fishes, and invertebrate animals are considered in due course. In relation to the parasites of man, the author gives a great deal of valuable statistical information which must be of special interest to the physician.

Altogether we cannot speak too highly of Dr. Cobbold's book, and congratulate the author warmly upon having so efficiently filled a gap in zoological literature, the existence of which had long been felt by all working naturalists and many medical men.

A Contribution to Agricultural Botany. By A. S. Wilson. (Aberdeen: J. Rae Smith, 1879.)

THE author of the small volume before us is already favourably known as an investigator of more than one obscure yet important problem connected with field-botany. The text of his present discourse is "turnip-singling." He approaches this subject in a characteristically careful manner, taking into account, as he does, a number of considerations which might easily escape the attention of an ordinary observer or experimenter. The object and manner of his experiments present no novelty; indeed, it seems to us that Mr. Wilson can hardly be fully aware of the immense number of trials which have been made, both in this country and on the Continent, in order to ascertain the best distance apart for swedes and turnips. However, experiments of this order certainly require frequent repetition in order that the influence of season, climate, soil, and manure, may be duly measured. Any one of these conditions may so affect the result as to invalidate a hasty conclusion drawn from one or two years' trials, even when such trials have been conducted, not in one locality, but in several. Mr. Wilson is quite

right in saying that "the theory of no farm plant has been worked out," and that "our turnip shows are conducted on no useful principle." But he is not equally correct in affirming that "the chemist of the Aberdeenshire Agricultural Association initiated a most important mode of teaching one aspect of cultivation," or that questions in agricultural botany "have usually been altogether subordinated to questions on the comparative efficacy of manures. Had Mr. Wilson known the range of work and style of teaching until lately prevailing at Cirencester, and for long and now in vogue in many agricultural colleges in America and on the Continent, he would have hesitated before making such statements.

While Mr. Wilson shows us how, under certain conditions, a larger weight per acre of roots was produced when the plants (both turnips and swedes) were singled so as to leave but 6 inches between them in the drills, although the drills themselves were 27 inches apart, he gives us no information as to the relative feeding values of the larger roots grown at 8 and 9-inch intervals, and the smaller but more numerous roots from the 6-inch intervals. Had the average weight of any of these sets of roots been exceptionally high or exceptionally low, this point would have been of much greater importance. For our object in growing such a crop as turnips or swedes is to obtain the most economical production of the greatest amount of wholesome and keeping food per acre. Very large roots are, we know, very watery, do not keep well, and contain certain nitrogenous and saline matters in excess, so as to become in this way also less desirable as food for farm stock. And it frequently happens that *all* the increase per acre obtained in the form of large roots is water or useless mineral matters. Thus, in all experiments, such as these of Mr. Wilson, fair samples of the crop from different plots should be reserved for analysis—water, ash, and albuminoid nitrogen, at all events, being determined in the produce of each plot.

Arithmetic in Theory and Practice for Higher and Middle Class Schools, &c. By Henry Evers, LL.D. (London and Glasgow: W. Collins, Sons, and Co., 1878.)

HAD Dr. Evers been entirely unknown to us, we should have had no hesitation whatever in saying that this is the work of a practical teacher; of one who has fully realised the difficulties of "teaching arithmetic," and by long experience and patient observation learnt to cope with those difficulties successfully. The arrangement is unquestionably good and in some respects original; the definitions and explanations are short and to the point, indeed we could wish in some cases the author had made them fuller; the problems are numerous and interesting and more of the ordinary daily business type than fanciful improbabilities; and the solutions as far as we have examined them remarkable for accuracy.

The author might have given another method for the extraction of the cube root applicable to all roots; those he gives are certainly the best we remember seeing in any text-book. The examination questions at the end will be found of very great value to those preparing for similar ordeals. The publishers have as usual given a good book a good dress as regards paper, type, and binding.

E. H.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

The Recent Weather

IT is not necessary to appeal to statistics to demonstrate the cold and sunless character of the weather nearly constantly experienced during the last few months, this being matter of the most ordinary observation; nevertheless some more exact information on the subject may not at the present time be unacceptable to the readers of NATURE.

The year 1878 until October had been generally warm, the temperature on the whole having been above the average in every month, excepting September, and it was very little below in this month. Then a period of cold set in. Beginning with 1878, November, the temperature has been in every month below the average, the deviation in some months being very large. The amount of sunshine, as recorded by Campbell's instrument, has also, since April, been in each month remarkably small. A few particulars, extracted from the Royal Observatory Records, by permission of the Astronomer-Royal, are given in the following table:—

Month, 1878–1879.	Deviation of mean temperature from average of twenty years.	Number of days on which the mean temperature was		Hours of bright sunshine.	Deviation of amount of sunshine from average of the two preceding years.
		Below the average.	Above the average.		
November ...	−3°·0	25	5	40·5	− 5·8
December ...	−7·1	25	6	16·3	− 0·4
January... ...	−6·9	26	5	14·8	−12·1
February ...	−1·5	16	12	31·7	− 2·9
March	−0·3	14	17	91·0	+ 4·8
April	−4·3	25	5	74·6	−36·5
May	−4·7	27	4	135·6	−21·0
June	−2·9	26	4	141·9	−83·3
July (to 19th)..	−5·8	19	0	52·9	−51·6

The sign − indicates *below* the average.

In every month the temperature has been below the average. The generally severe character of all the months, excepting February and March, is well shown in the column giving the number of days on which the temperature was below the average. From April 1 to July 19, a period of 110 days, 97 were below the average. And during the same period the hours of bright sunshine numbered only 405·0, which is 192·4 hours less than the average of the same period in the two preceding years, or 0·68 only of the amount registered in those years.

Royal Observatory, Greenwich, July 23 WILLIAM ELLIS

Some Remarks on the Rev. J. G. Wood's Explanatory Index to "Waterton's Wanderings"

1. THE name of the Indian tribe mentioned ought to be *Tamanacos* and not *Jamunacs.*

2. The botanical name of the arrow-reed is *Gynerium* (not Gynœcinm, p. 372).

3. (P. 378).—The Balata gum has reached the English market long ago, though it may have disappeared again. If I do not mistake there existed about 1864 even a Balata Gum Company, in which Messrs. Silver and Co. took the lead. We have in Venezuela (State of Maturin) the same tree, where it is called Purvio. Mr. d'Azevedo, of Maturin, sent several times quantities of the gum to Hamburg, but I am informed it did not pay.

4. (P. 380).—The *Camoudi* is *Eunectes murinus* (not marinus). Mr. William Crookes in his article "Gravitation as a Factor in the Organic World" (*Journal of Science*, January, 1879, p. 42), calls it aquatic, and says that it inhabits the rivers of South America. This is certainly wrong; it is generally found near the water, and swims very well, but is by no means an aquatic animal.

5. (P. 381).—*Copaiva* is an oleo-resin, and should not be called a *gum*. There is on p. 461 a misprint in the name of the tree from which it is obtained. It is *Copaifera pubiflora*, Benth., not *C. publiflora.*

6. (P. 383).—The name of the describer of the birds of Trinidad is *Léotaud* ("Oiseaux de l'Ile de la Trinidad," Port d'Espagne, 1866).

7. (P. 384).—The castor-oil plant belongs to the family of Euphorbiaceæ, but not to the tribe of Euphorbiæ (or better Euphorbieæ).

8. (P. 385).—Read *Anolis* instead of *Anolius.*

9. (P. 394).—The coffee-tree does not belong to the "useful

group of Cinchonaceæ," which is distinguished by numerous seeds in each carpid, though both are included in the same family of Rubiaceæ.

10. (P. 407).—The conical mound of the Flamingo is not at all an error in natural history. I have seen several of these nests with the eggs on the top of the heap on the Roques Islands, north of La Guaira.

11. (P. 412).—*Vulpes cancrivorus.* There is no species of true *Vulpes* in South America, if we follow the distinction established by Burmeister ("Syst. Uebersicht der Thiere Brasil.," i. 92), and the animal in question is undoubtedly the *Canis cancrivorus*, Desm.

12. (P. 431).—"Kurumanni Wax. This is composed of the wax of a wild bee (*Ceroxylon andicola*), mixed with a pitch-like substance obtained from several trees, chiefly the Maam-tree." It is scarcely possible to believe that the accomplished editor of the "Wanderings" should have penned these lines, where a noble palm of the Andes is changed into a wild bee. The latter is most likely a species of *Melipoma*. The *Kurumanni wax* may be identical with a pitch-like substance, called *Caraman*, *Paraman*, or *Peraman* in Venezuelan Guayana, and which is obtained from *Moronobœa coccinea*, Aubl.

13. (P. 434).—The mahogany tree belongs to the family of Meliaceæ, but not to the group of Cedraceæ (or better Cedreleæ).

14. (*Ibid.*).—*Maribunta* is not a Portuguese word signifying a wasp. In Brazil the word *maribondo* is used for a certain species of wasp, but the name is taken from the Tupi language.

15. (P. 440).—*Mosquito.* Even in popular works on natural history authors should call everything by its real name, and it is therefore altogether wrong to speak of the *bites* of mosquitoes; *sting* would have been just as short, and evidently more correct.

16. (P. 447).—*Pataca.* Perhaps we may read *paraca*, one of the names of *Ortalida motmot*, Wagl.

17. (P. 473).—*Sting Ray. Trygon pastinaca* is a maritime species; but there are several other ones in South American rivers, as *Tr. hystrix*, &c.

18. (P. 473).—*Sugar cane* is *Saccharum* (not *Saccharinum*) *officinarum.*

19. (P. 474).—"The tiger-birds derive their popular name from the peculiar cry which they utter." What powerful lungs they must have, these tiger-birds, in order to be able to roar like a jaguar! This singular blunder might have been avoided by reading carefully what Waterton says (p. 195), that it has no song, its name being due to the black spots on a yellow ground on breast and belly.

20. (P. 475).—The tortoise of Guayana, as far as I know, is *Testudo tabulata*, called *Morrocoi* in Venezuela. *Cistudo carolina* is a North American species.

21. (P. 236).—*Chigoe.* What Waterton says of the hatching of this animal *within* the body of man is certainly not true. The eggs are developed outside, the larvæ leading a free existence.

Some of the foregoing remarks refer to mere clerical errors (a good many less important ones having been passed over in silence); but there are unfortunately not a few inaccurate, and even wholly erroneous statements which we were sorry to find in this *Explanatory Index*. A. ERNST

Caracas, May 15

Swift's Comet.—Williams College Observatory

I HAVE computed a set of elements of the comet lately discovered by Mr. (now Dr.) Swift. They are from observations made by Prof. Lewis Boss, Director of the Dudley Observatory at Albany, on June 24, June 30, July 8. They are these:—

T April 27·1801, M.T. Washington.

log. q	9·950918	
ω[1]	3° 28′ 13″·0	M.Eq., &c., 1879·0.
☊	45° 41′ 10″·5	
i	107° 1′ 53″·6	

For the middle observation $c - o$ $\Delta\lambda + 0''\cdot6$

$\Delta\beta + 0''\cdot3$

Or in space, both co-ordinates, about $0''\cdot5$.

They were computed by Olbers' method, afterwards varying *M* by the regular rule. A trifling change of *M*, which I have not now time to make, would bring a closer representation of the middle observation; say to about $+0''\cdot2$ and $-0''\cdot1$ in longitude and latitude respectively.

I am happy to say that the observatory of this college is to be repaired and put into active operation. It is about forty years old—the oldest I believe in the United States—and was built by the late Prof. Albert Hopkins. It now contains a $7\frac{1}{4}$ inch equatorial, an early work of Clark; a $3\frac{1}{2}$-inch Simms transit, of the style of forty years ago, with a very poor object-glass; and a sidereal clock by Molyneux and Cope, still in good order. I have been authorised by the Hon. David Dudley Field to procure a meridian circle with telescope of about 5 inches aperture.

The gentleman just named is the founder of my professorship, the "Field Memorial Professorship of Astronomy," and it is probable that in future a portion of the duties of that professorship will consist in making observations, and in their complete discussion. TRUMAN HENRY SAFFORD

Williams College, Williamstown, Mass., U.S.A., July 11

[1] Dist. of perihelion from node.

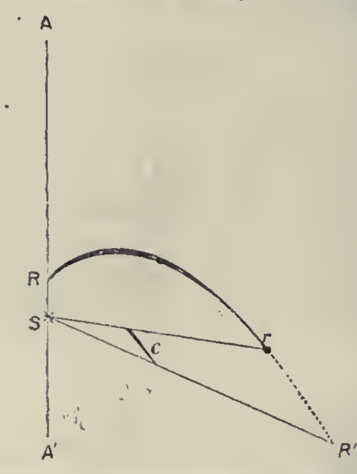
Electric Lighting

IN the evidence given before the Committee on Electric Lighting, some mention was made of the difficulty of equalising the light over any considerable area; but it is worth while to remark that by a simple form of reflector it is possible to make the light very approximately uniform over an area whose radius is twice the height of the lamp above the ground. For imagine a sphere with the lamp as a centre and its height above the ground for radius. Supposing the lamp radiates equally in all directions, the surface of this sphere will be uniformly illuminated, and its surface has an area $4\pi h^2$. If now we take a plane circular area about the foot of the lamp-post with radius R such that—

$$\pi R^2 = 4\pi h^2 \text{ or } R = 2h,$$

it is plain that by a proper distribution by reflection of the light which would pass through the imaginary sphere outside the solid angle subtended at the lamp by the plane circular area, the illumination over that area may be made uniform and equal in intensity to that near the foot of the lamp-post.

To find the proper form for the reflector, which is of course a surface of revolution, it is necessary to find the angle which



each zone of the reflector subtends at the lamp in terms of the angle in which the light is reflected by it. This is given by the equation—

$$\sin\phi\, d\phi = \left(\frac{1}{\cos^3\theta} - 1\right) d\theta,$$

with the condition $\phi = 0$, when $\theta = \tan^{-1}2$, where taking the lamp-post as the polar axis, the upper end being north, $(90 - \phi)$ is N. latitude of that zone of the reflector which sends out its light in S. latitude $(90 - \theta)$. The polar differential equation of the curve for the reflector may then be easily found; it is—

$$\rho \frac{d\phi}{d\rho} = \cot \frac{\theta + \phi}{2}.$$

A figure of the curve is given below at R R′. The surface of the reflector is swept out by the revolution of R R′ round A A′. The dotted portion r R′ should be replaced by a separate zone shown at c, but the chief value of this will be as a screen to prevent the light from being visible at low altitudes, the small quantity of light reflected by it merely going to reinforce the illumination in the immediate neighbourhood of the lamp. Such reflectors might be applied with great advantage to powerful lights placed at considerable elevations. A. MALLOCK

Brampford Speke, near Exeter, July 14

Did Flowers Exist during the Carboniferous Epoch?

THE systematic position of the genus *Breyeria*, founded for the reception of a fossil insect, having formed the subject of a recent discussion in NATURE (vol. xix. pp. 554, 582), I have just visited Brussels to examine the original type. Through the courtesy of M. de Borre I have been allowed to submit it to a careful microscopical scrutiny, and have sketched, with the aid of a camera lucida, a considerable part of it on a large scale. The facies of the neuration is extremely similar to that of genera allied to *Palingenia* of the Ephemeridæ, resembling theirs not only in the relative abundance of cross-veinlets, but also in the manner of the aberrations of abnormal cross-veinlets. The *Palingenia* group is sufficiently elastic to comprise *Breyeria*, although this differs in detail to some extent from any known genus of recent Ephemeridæ.

May I be allowed to suggest that if photographs of fossil insect-remains be taken for critical purposes, it would be advantageous to execute them on a scale of considerable enlargement. In the present instance it was far easier to distinguish nervures from mechanical depressions in the stone when a 3-inch object-glass was employed, than when a 4-inch glass was in use. These are the lowest powers that I have with me, excepting simple lenses. *Apropos* of fossil insects, there is in Baron E. de Selys Longchamp's collection, a species of recent *Homoptera*, which is likely to be of interest to palæontologists. At first sight it resembles a fragmentary specimen of Ephemeridæ so closely that it was actually reserved for my inspection as such. Viewed through a weak lens, it would appear from its anterior wings to be a representative of the Planipennes, allied more or less to *Panorpa* perhaps. A more careful examination, however, reveals its rostrum and other characters distinctive of its real nature. Its exact affinities have still to be ascertained; but in all probability it is something new and extraordinary. A. E. EATON

Rotterdam, July 24

The Papau

I WAS surprised to read Capt. Oliver's statement in NATURE, vol. xx. p. 241, that the papau (*Carica papaya*) is not eaten by birds in Bourbon and Mauritius. In Samoa it is eaten largely by birds—especially by *Sturnoides atrifusca*, and also by bats of the genus *Pteropus*. The seeds of this fruit appear to have been carried by the agency of birds over at least a great portion of the islands. I have seen many places where the virgin forest has been cleared, and in every instance—as far as my memory serves me—a thick crop of *Carica* appeared as soon as the clearance was made. They do not grow while the forest stands, but spring up in thousands as soon as light is let in to the soil.

Intellect in Brutes

I HAVE just been watching with care the action of a party of ants, exhibiting an intelligence nearly allied to reason, if indeed it be not "reason."

Clearing the shelf in a hothouse, two large cockroaches were caught, killed, and left lying on the small gravel with which the shelf is covered. This shelf is four feet from the floor, and the nest of the ants is behind a slab at the end of the house. When the cockroaches were killed, very few ants were upon the slab, but they must have communicated to others the discovery of the treasure, for in about twenty minutes a swarm of ants emerged from the nest, climbed the wall, gained the shelf, and there, dividing into two parties, proceeded to take possession of the dead bodies.

To understand the significance of what I am about to relate, it is necessary to form a distinct conception of the comparative sizes of the ant and the cockroach. The ant was the smallest of its kind; the body of its prey was nearly two inches long and half an inch in width. The proportions were to each other as would be those of a man to the dome of St. Paul's. Their purpose was to carry these two huge carcases to the nest, and to accomplish this it was necessary, first, to draw them for a space of ten inches over rough gravel, then along a smooth board for two feet, then to drop them to the floor beneath, then to drag them over some very rough rubble for one foot four inches, and finally to pass them between two slabs of wood into the nest. This extraordinary feat they performed successfully. It was accomplished thus: They surrounded the corpse of the dead cockroach and seizing it with their mandibles, moved it onward a little way. It was lying inclined on its side. When moved, the projecting edges of the side hitched in the stones and prevented progress.

I observed that, on some larger stones near the spot, half a dozen ants stood looking at the work, but taking no part in it. When the hitch occurred, and always afterwards when there was an obstacle, these "surveyors" left their stations, went to the workers and then returned to their place of observation. They were manifestly directing the operation and instructing the labourers; and they as manifestly made some communication to the labourers, for forthwith these changed their plan. They now turned the cockroach on its back, and in this position they moved it onward triumphantly for three or four inches. How? They stood round the corpse at precisely equal distances apart and by a common effort dragged it forward. They pulled together, apparently in obedience to a signal from the "surveyors," just as men shout when *they* want to pull together.

Another obstacle. Three pieces of gravel bigger than the rest lay in their path. What to do now? They crept under the carcase and lifted it by planting the hind feet on the floor and standing upright, sustaining the load with their heads, while a party mounted the opposing stone, seized the tail, and tried to drag the burden up. But in vain. It was too much for their strength and the load was dropped.

Then the ants that had been directing again moved from their places and ran rapidly about in all directions, as if seeking some more easy passage. Having found one they remounted their post of observation and it may be assumed that they gave some intelligent orders to the labourers, for immediately these resumed their hold upon the carcase and moved it forward in the new direction indicated.

Similar obstacles occurred four times in the course of their journey over the gravel, and on each occasion the same proceedings were observed. Their patience was inexhaustible. At length the body was successfully brought to the smooth edge of the wooden shelf, whence it could be dropped to the floor beneath. But it was necessary to select a fit spot for this purpose, inasmuch as the floor was strewn with bricks and plants. In fact there was but one open space of about four inches square into which the body could be sent so as to be carried securely to its destination. To reach this spot they had to drag the burden along the ledge for a space of 17 inches. In this journey balance was repeatedly lost and the carcase would have fallen, but that it was seized, held, and dragged back by their united efforts. At length, having arrived at the place where its fall would be upon the open floor, it was dropped by all at once losing their hold of it. But previously to their doing so, the "surveyors" ran down the wall to the floor and posted themselves directly under the ledge on which the body lay (4 feet above them). There they waited its fall. I think their business there was to see if all was safe and the place really fit for the purpose, and that they made some communication as to the precise spot to be chosen for the fall, for the ants who bore the corpse shifted it two or three times before they let it down. Then all followed, running down the wall, seized their prey again, and in half an hour carried it a distance of nearly 3 feet to the entrance of the nest.

But here another difficulty occurred. It could not pass between the boards when lying upon its back. They turned on its side and tried again. Again they were baffled; the legs hitched. So they turned it on its back once more, bit off the legs, which were carried into the nest by other ants, and then the body was turned on its side and taken through the narrow way into the nest. To me, looking at it with the eyes of a psychologist, all this seemed to indicate the exercise of a *reasoning* faculty. They devised new methods of meeting new circumstances. It satisfied me, also, that ants at least have means of intercommunication. The fact of the find was obviously communicated by the discoverers. The workers manifestly acted under instructions and obeyed commands.

My object in this communication is merely to place upon record a very remarkable proof that the lower animals have intelligence very like our own. EDWARD W. COX

Moat Mount, Mill Hill, N.W., July 26

AS you are publishing notices of intelligence in brutes perhaps the following example of memory in a bird may be interesting. When I returned from the Pacific about two years ago, I brought

a sulphur-crested cockatoo (*Cacatua galerita*) from Australia. Soon after my arrival in England I had occasion to cut his wing, and this destroyed all his former friendly feelings towards me. On my removal from Blackheath to Dublin, I placed him for a few weeks in the Zoological Society's Gardens, Regent's Park. Being in London in May I brought him with me on my return to this city. I went to the Gardens for him myself, and was interested and somewhat pleased to find, on speaking to him, that he had apparently forgotten me. On my way, in a cab, to the hotel where I was staying, he was very friendly; but on my arrival there, as soon as I took off my hat, it was evident that he recognised me, for his old manner at once returned. On arrival here he appeared to remember my children, and resumed his former friendliness towards them, but he still regards me as his enemy.

Proceedings of the Aberdeenshire Agricultural Association, 1878

YOUR article (vol. xx. p. 288) touches a subject of vital importance to the farmer in these bad times, and I hope you will follow it up by an appeal to Mr. Lawes and to the Royal Agricultural Society of England to institute a parallel and independent course of experiments, in order to test the conclusion in regard to phosphatic manures announced by the Scotch Association.

The possible presence of humic, carbonic, and other acids in more than usual proportion in Aberdeenshire soil and water has often occurred to me as accounting for the similarity of results between those local experiments of soluble and insoluble phosphates, but it can hardly be denied that a case has been established for further experiments. The fact that acid and manure makers have a direct pecuniary interest in the existence of a prejudice in favour of *soluble* phosphate might alone have led farmers to require some evidence before spending their money under such scientific dictation, but now that they have three years' experiments testifying distinctly against the doctrine, they may surely look to their advisers for something more than bare assertions on authority that a "mineral phosphate is of little or no value as a maure until it has been rendered soluble by acid in course of manufacture." ALFRED S. JONES

Wrexham, July 27

Spicula in Helix

WHILST dissecting, a few days ago, a common garden snail (*Helix aspersa*), I came across two calcareous spicula, lying immediately under the "albuminiparous gland," which I cannot find mentioned in any of the text-books. I at once dissected three other snails of the same species, and in two I found no spicula, while in the third I found one lying in the same place as the two before-mentioned. Can any reader of NATURE tell me whether these are of the same nature as the diffused spicula of Doris, or if not, of what nature they are? They could not have been "spicula amoris" (Huxley) of the dart-sac, as they were not contained in any sac at all, but were lying free in the above position. EDWD. B. PARFITT

3, Waterfield Terrace, Blackheath, S.E.

GENERAL RESULTS OF EXPERIMENTS ON FRICTION AT HIGH VELOCITIES MADE IN ORDER TO ASCERTAIN THE EFFECT OF BRAKES ON RAILWAY TRAINS[1]

II.

SOME special experiments were made with blocks of small area. The brake-blocks generally used in these experiments were 12 inches long, by 3 inches wide, giving a surface of 36 square inches; the small brake-blocks were made so as to afford a surface of pressure against the wheel of only one-third of this amount, or 12 square inches, thus making the pressure per square inch three times as great as before. The diminution of surface was obtained by casting projections upon the face of the block. The author is not prepared to say that any greater coefficient of friction was obtained by the extra pressure per square inch, although in one of the experiments, at a velocity of sixty miles an hour, the rotation of the wheels was arrested by these blocks, whilst this effect had not been produced at that speed in other experiments. The experiments on this form of block were stopped because the blocks were entirely worn down in the course of about twelve experiments.

Mr. Rennie showed[1] that high pressures per square inch produced a greater coefficient of friction between surfaces either moving very slowly or nearly at rest; but it must be borne in mind that the author's experiments were made with high velocities, whereby a serious element of disturbance is introduced, viz., the grinding away of the surface; and it is therefore probable that the increase in the coefficient of friction due to increased pressure, may have been neutralised by the lubricating effect of the fine particles ground off the surfaces.

While no certain opinion can be expressed as to the relation which the coefficient of friction bears to pressure, so far as these experiments are concerned, it is quite clear that in proportion as the pressure is increased or diminished so will the actual friction obtained be increased or diminished. When the friction which exists between the brake-blocks and the wheel reaches a certain point, the wheel ceases to rotate, and becomes fixed. This point is reached when the frictional resistance of the blocks exceeds the adhesion between the wheel and the rail if the speed is kept up; or, if the speed is slackening, when it exceeds the adhesion between the wheel and the rail, plus the effort required to retard the rotation of the wheel equally with the retardation of the train; and the excess of resistance then acts as an unbalanced force, tending to destroy the momentum of the wheel.

Usually there are in a train a certain number of vehicles braked and a certain number unbraked. If the brakes acted on all the wheels, then the rotating momentum of the wheels does not add to the distance in stopping a train, because that momentum can be acted upon by the brakes directly, without in any way affecting the adhesion of the wheels to the rails. It simply requires an additional amount of brake-block pressure.

With the unbraked portion of a train the rotating momentum of the wheels is an addition to the momentum due to the weight of the train (including therein the actual weight of the wheels), which cannot be utilised for retardation; and it therefore seems important that there should be brakes on every wheel of a train.

As it thus appears that it is the adhesion which governs the retardation which the brake-blocks can exert upon wheels, it is manifest that the pressure brought to act on the brake-blocks should never give an amount of friction which exceeds the adhesion. At a high speed, however, the pressure required to produce a degree of friction equal to the adhesion is much greater than what is required at a low speed.

The following table gives approximately the proportion which the pressure to be applied to the brake-blocks should bear to the weight upon the braked wheels, with coefficients of adhesion between wheel and rail varying from ·30 to ·15 of the weight on the wheels :—

Ratio of Brake-Block Pressure to Weight on Wheels

Speed.		Approximate ratio of total pressure on brake-blocks to total weight on braked wheels.			
Feet per second.	Miles per hour.	Coefficient of adhesion 0·30.	Coefficient of adhesion 0·25.	Coefficient of adhesion 0·20.	Coefficient of adhesion 0·15.
11	7½	1·20	1·04	0·83	0·60
22	15	1·41	1·18	0·94	0·70
29	20	1·64	1·37	1·09	0·82
44	30	1·83	1·53	1·22	0·92
59	40	2·07	1·73	1·38	1·04
73	50	2·48	2·07	1·65	1·24
88	60	4·14	3·47	2·77	2·08

[1] Continued from p. 295.

[1] *Phil. Trans.* for 1829, p. 159.

It will be seen that, when the adhesion equals ·30 of the weight, a pressure equal to 1·2 of the weight would skid the wheel at $7\frac{1}{2}$ miles per hour, whilst a pressure equal to 4·14 times the weight would be required to do so at 60 miles per hour.

On the other hand, if the adhesion is only ·15, the pressure requisite to skid the wheel would be only ·60 of the weight at $7\frac{1}{2}$ miles per hour, and 2·08 of the weight at 60 miles per hour.

Thus the efficiency of a brake depends upon the pressure being proportioned to the speed and to the adhesion. If the adhesion were always uniform, the rule would be very simple; but this is not the case.

The adhesion of the wheels to the rails varied according to the materials, that is, whether the train was travelling upon iron or steel rails; and according to the state of the rail, whether dry, wet, or sanded.

On dry rails it was found that the coefficient of adhesion of the wheels was generally over ·20. In some cases it rose to ·25, or even higher. On wet or greasy rails, without sand, it fell as low as ·15 in one experiment, but averaged about ·18. With the use of sand on wet rails it was above ·20 at all times; and when the sand was applied at the moment of starting, so that the wind of the rotating wheels did not blow it away, it rose up to ·35, and even above ·40. Consequently, the retarding effect of the brakes would be greatly increased, were means devised for placing sand under every wheel to which a brake is applied, during the progress of a stop.

The effect in stopping a train is greatest when the friction between the brake-blocks and the wheels amounts to a quantity just short of the resistance caused by the adhesion, because as soon as the brake-block friction exceeds the adhesion, the wheel becomes fixed and begins to slide. In order, however, to secure the best results in stopping, it is obviously necessary that the brake-block pressure should be regulated to give a friction about equal to the adhesion of the wheels at every stage during the progress of a stop.

There is no reason why, in the progress of mechanical science, these conditions should not be regulated by a self-acting arrangement.

Mr. Westinghouse has devised a valve to regulate the pressure between the blocks and the wheels. The principle of the valve is, in the first place, to prevent the actual friction from exceeding the adhesion at any point; and in the next place, whilst allowing the fullest amount of pressure necessary to produce the maximum friction to be applied to the brake blocks when the brakes are first put on, that is to say, when the speed is high at the commencement of a stop, to reduce that pressure gradually during the progress of the stop, so as to maintain as nearly as possible a uniform amount of friction.

As the adhesion varies it is necessary to consider what amount of adhesion for purposes of retardation can be safely calculated upon.

The following table shows the distances required to stop a train on a level line from a speed of fifty miles per hour, with a retarding force of from 5 to 30 per cent. of the total weight of the train:—

Percentage of retardation.	Yards run at fifty miles per hour.	Percentage of retardation.	Yards run at fifty miles per hour.
5	$555\frac{2}{3}$	18	$154\frac{1}{3}$
10	$277\frac{2}{3}$	20	139
12	$231\frac{1}{3}$	25	111
15	185	30	$92\frac{2}{3}$

If the brakes act upon each wheel, then a retardation of 10 per cent. of the load carried by each wheel—counting the rotating momentum as part of the weight—will stop a train in $277\frac{2}{3}$ yards.

If the brakes act upon only half of the weight of a train, a retardation of 20 per cent. would have to be exerted upon the braked half to produce the same result. As pointed out, 20 per cent. adhesion is rather above the average obtainable, while 25 per cent. is the highest result obtained under the most favourable circumstances at any considerable speed, or except when sand was applied to wheels moving slowly.

The above table should be carefully noted, for it will be seen that, even if brakes act upon all wheels, 25 per per cent. retardation will only give twenty-eight yards better result than 20 per cent., or if half of the train only be braked, it will give fifty-nine yards advantage.

A consideration of this feature of the brake problem points out (1) that the advantage to be gained by trying to obtain above 20 per cent. retardation on each wheel is greatly overbalanced by the risk of "skidding;" and (2) that it is far easier and safer to make a stop in 250 yards from fifty miles per hour with the whole train braked, than with brakes upon only half of the train.

The following are some of the results of the earlier experiments, obtained with Mr. Westinghouse's pressure-regulator:—

No. of experiment.	Gradient.	Speed. Miles per hour.	Condition of stops.			Total brake block pressure, P, on the four wheels.			Percentage of brake block pressure to weight on wheels.		Observed coefficient of friction between brake blocks and wheels on one pair of wheels.			Mean retardation calculated from stop.
			Time of stop. Seconds.	Distance run in yards.	Distance reduced to fifty miles per hour. Yards.	Maximum.	Middle of experiment.	End or at skid.	Maximum at commencement of experiment.	Minimum at end of experiment.	At moment when maximum pressure was obtained.	At middle of experiment.	At end of experiment.	
1	$+\frac{1}{264}$	60	$12\frac{3}{4}$	171	118	32370	31200	23010	160	114	·129	·125	·241	23·3
2	$+\frac{1}{311}$	60	$12\frac{1}{4}$	167	116	32760	30810	29250	162	145	·145	·161	skid	23·9
3	$+\frac{1}{330}$	55	$10\frac{1}{2}$	141	116	28470	27690	16380	141	81	·160	·176	·31	23·8
4	$-\frac{1}{400}$	57	$18\frac{1}{2}$	223	171	24570	15990	7800	122	39	·157	·158	·35	16·8
5	Level last thirty yards $-\frac{1}{170}$	55	18	227	194	17550	14430	8190	87	40	·161	·182	·309	14·3

In the second experiment the pressure was not reduced with sufficient rapidity to prevent the skidding, and in the fourth and fifth experiments the pressure was insufficient at the beginning of the experiment. From these and

other experiments it was found that the best results were obtained in cases where the pressure applied at first was from about 1¾ to twice the weight on the wheels, and where the reduction of the pressure was effected with sufficient rapidity towards the end of the stop to prevent the friction being sufficient to skid the wheels.

The necessity for the instantaneous application of the maximum brake-block pressure throughout the train is evident from the fact that, at a speed which is frequently obtained, namely, 60 miles per hour, a train passes over 88 feet each second; therefore the loss of two or three seconds in applying the brakes means often the difference between safety and danger, and the rapidity of a stop largely depends upon the rapidity with which all the brake-blocks can be brought to act against the wheels of a train.

This points to the advantage of being able to move the brake-blocks with great rapidity from their position of inaction to that of contact with the wheels; because it is essential to provide that the brake-blocks, when out of use, shall be removed to a distance from the wheels sufficient to prevent the possibility of their dragging against the wheels, and thus retard the progress of the train. The question of the rapidity with which brakes can be applied in practice is thus one of much importance.

Some experiments were made in October, 1878, upon the North Eastern Railway, on a train fitted with the vacuum brake, and one fitted with the Westinghouse brake to ascertain the time which was required after moving the brake-handle to set the brakes with various degrees of force in different parts of the train. The following table shows the result arrived at :—

Place of experimental van from engine.	Vacuum brake.				Westinghouse automatic brake.			
	Commencement of movement of blocks.	Half on.	Three-quarters on.	Full on.	Commencement of movement of blocks.	Half on.	Three-quarters on.	Full on.
	secs.	secs.	secs.	secs.	secs.	secs.	secs.	secs.
1st vehicle	⅓	3	7	11	¼	⅝	¾	1½
7th ,,	2	6½	8⅓	14	1	1¾	2	2½
13th ,,	3⅓	7½	9⅓	14	1¾	2¾	3⅛	3½
21st ,,	5½	17	30	—	3	4½	5	5½

A long interval of time between brakes coming on at the front and rear of a train may become a source of danger; and improvements have been introduced in both the vacuum and Westinghouse apparatus since that date to reduce the interval as shown by the experiments.

In the Westinghouse brake a simplified triple-valve has been adopted, the friction has been reduced by the use of an enlarged pipe and by the removal of bends in the connections between the carriages; by these alterations the interval of time required to put on the brakes, as shown in the above table, has since been reduced by nearly one-half, and an experiment recently made on the application of the brake in rear of a train of twenty-four vehicles on the Western Railway of France showed that the pressure commenced to be brought on in one second, and was fully on in two and a half seconds from the time of first moving the brake lever.

The importance of simultaneous action of the brakes in every part of a train arises from the fact that the train is not a rigid mass, but is made up of separate vehicles connected by means of spring draw-bars and buffers. The length of the train can thus be modified to a certain extent by the degree of compression of these springs. In a recent experiment on the North-Eastern Railway the train consisted of twenty-four carriages, and the whole extent to which the buffers could be compressed amounted to 35 feet. A train travelling at 60 miles an hour moves at 88 feet in a second. If the brakes act on the front part of the train before they affect the hind part the speed of the front carriages may be diminished by 10 to 18 feet in a second, whilst the hind part moves on with undiminished speed; thus the hind part may press against the front part with a force of from 12 to 20 foot tons for every ton weight of the hind vehicles. The buffer springs would be compressed by this force and remain so till the brakes acted equally on all the wheels, when a reaction of the buffer springs would take place; this reaction creates the violent jerks often felt with continuous brakes, and occasionally results in fractures of couplings and draw-bars. In a perfect brake the application would be instantaneous, and simultaneous on all the wheels of a train.

It is beyond the scope of this paper to enter fully into the merits of different kinds of brakes, but it may be convenient to sum up what seem to be the requirements of a perfect brake.

1. It should be fitted to act upon each wheel of the engine, tender, and every other vehicle in a train of any length. The brake-blocks, when out of action, must be kept a certain distance away from the wheels, in order to prevent any liability to drag against the wheels; and this distance, after being once adjusted, gradually increases by the wear of the blocks, and often exceeds three-quarters of an inch; while the springing of the brake-gear under great strain also adds to the extent of movement required in the brake force before the blocks are fully applied. Hence the brake gear should be so adjusted as to be capable of moving the brake blocks instantaneously through a space of one inch.

2. However brought into action, it should be capable of exerting upon the blocks of each pair of wheels, within two seconds, a force of twice, or at the very least one-and-three-quarter times, the load on those wheels.

3. The brake-block pressure acting on each wheel should be regulated so that the friction between the brake-block and the wheel may always be limited so as not to exceed the adhesion between the wheel and the rail; by which means it will produce the maximum effect at each moment of its application.

4. The brake-block pressure should be capable of being applied by engine-driver or by guards.

5. The engine, tender, and vehicles should each carry its own store of brake-power, which should be independent of the brake-power on any other vehicle.

6. The brake-block pressure should be automatically applied to every vehicle by the separation of the train into two or more parts, and it should also be applied by the act of the wheels of any carriage leaving the rails.

7. The brake-block pressure should be automatically applied by such failure of the connections or appliances as would render it afterwards incapable of application until the failure had been remedied.

8. The brake-block pressure should be capable of application with any degree of force up to the maximum, and it should be capable of continued action on inclines, or, of repeated applications at short intervals at junctions and stations.

In addition to these requirements, the questions of cost, durability, convenience in operation, and other essential points, will of course come under consideration.

The experiments which have been here described were made on trains travelling under conditions which were necessarily continually varying, both in respect of the condition of the rails and other matters; and they therefore contained many elements beyond the reach of calculation. It is hoped that some opportunity may arise, ere long, for resuming expeiiments on friction at high velocities under conditions whence these elements of disturbance may be eliminated. Meanwhile it is evident

that a continuous brake, capable of being applied simultaneously to every wheel of a train under the conditions which have been enumerated in this memorandum, is a much more practical and scientific method of bringing a train to rest than the old plan of concentrating the brake-power in two or three heavy brake vans placed in different parts of the train, and leaving the rest of the wheels without brakes.

The advantage which thus evidently ensues from utilising the adhesion of every wheel of a train for the purpose of stopping a train suggests the further consideration as to whether it would not be a more scientific arrangement, as well as more economical in regard to the permanent way of railways, to utilise the adhesion of every wheel of a train for causing the train to move forward, instead of depending for the moving force upon the adhesion of one heavy vehicle alone, viz., the locomotive. Experiments connected with the action of brakes on railway trains require very delicate apparatus; the credit of the design of the apparatus used in these experiments belongs to Mr. Westinghouse. The efficiency of the arrangements for making the experiments is due to the London, Brighton, and South Coast Railway Company, as represented by Mr. Knight, their general manager, who afforded every facility for the use of the line, and by Mr. Stroudley, the locomotive engineer of the Company.

DOUGLAS GALTON

OUR ASTRONOMICAL COLUMN

THE COMET OF 1532.—This comet, the second of the five observed by Apian, as described in his rare work, the "Astronomicum Cæsarium," has been the subject of much computation and discussion in connection with its long-assumed identity with the comet of 1661 observed by Hevelius, to which attention was directed by Halley when he published his "Synopsis of Cometary Astronomy." We read: "Halley was apt to believe that the comet of 1532 was the same with that observed by Hevelius in the beginning of 1661, but Apian's observations, which are the only ones we have, are too inaccurate to determine anything certain from them in so nice an affair." Pingré fully believed in the identity of the comets of 1532 and 1661, and in his "Cometographie" has endeavoured to point out several previous appearances of the same body, as in the year 1402, when he expresses his conviction that the great comet recorded in so many of the European chronicles about Easter was no other than the one in question. Between the perihelion passages of 1532 and 1661 is a period of 128¼ years, and so the return of the comet was long expected about 1789. Shortly before this year, however, the rediscussion of the observations of 1532 and 1661 was made the subject of a prize by the Paris Academy of Sciences, which was gained by Mechain.

His calculations threw much doubt upon the presumed identity of the comets, indeed were pretty generally considered as decisive against it. Olbers also recomputed the orbit from the observations of 1532, and although he found one much closer to that of the comet of 1661 than Mechain had done, seems to have arrived at the conclusion that the comets were not identical. Nevertheless, as the year 1789 approached, sweeping-ephemerides were prepared to facilitate a search, the then Astronomer-Royal, Dr. Maskelyne, taking a part in this work. The search was ineffectual, no one of the comets which appeared about that year presenting any indications of being the expected body.

It is probable that the elements of the comet of 1532 are open to even greater uncertainty than has been usually supposed. Apian's observations are clearly affected with large errors, yet we are under the necessity of relying upon them as the best data available, neither the vague and contradictory observations (if they deserve the name) by Fracastor at Verona, nor those of Vogelin at Vienna, being of service in the determination of a more certain orbit than can be inferred from the observations in the "Astronomicum Cæsarium." Apian appears to have observed at Dresden, and the times of observation are given by altitudes of Regulus and Arcturus; the amplitudes of the comet (S. to E.) and its altitudes are recorded. The positions of the stars for 1532·0 were:—

	Right Ascension.	Declination.
	° ′	° ′
Regulus	145 49·7	+14 12·1
Arcturus	208 35·2	+21 40·1

Assuming Apian's station to have been in longitude 0h. 54m. 56s. E. and latitude 51° 3′·7, his data furnish the following places, which, except for the first day, do not differ more than might have been expected from Pingré's reductions:—

	G.M.T.	Right Ascension.	Declination.
		° ′	° ′
1532, October	1·6635 ...	155 43·8 ...	−4 26·9
	2·6491 ...	160 10·7 ...	−3 20·3
	30·6699 ...	206 3·6 ...	+3 48·6
	31·6939 ...	208 48·3 ...	+4 20·6
November	7·6747 ...	218 51·1 ...	+5 55·8

We subjoin an orbit depending on the observations of October 2, 30, and November 7, and also Olbers' elements from Hindenburg's *Magazin für Mathematik*, 1787:—

	New Orbit.	Olbers.
Perihelion passage ...	Nov. 3·1355 G.M.T. ...	Oct. 18·3324
	° ′	° ′
Long. of perihelion	174 51	111 48
,, ascending node ...	132 32	87 23
Inclination	57 41	32 36
Perihelion distance	0·6736	0·5192
Motion	Direct.	Direct.

The comparison with the above-observed positions is slightly in favour of Olbers' orbit, though this differs from the place for November 7 by − 1° 40′ in longitude and − 4° 36′ in latitude. Still it will appear that Apian's observations may be represented within their evident limits of error, by orbits which differ widely.

The Chinese observed this comet from September 2 to December 25, according to the extracts from their annals which have been given by E. Biot and Williams: on the former date, according to Olbers' elements, the comet was in longitude 98°, latitude 47° south, distant from the earth 0·78, and on the latter date in longitude 249°, latitude 16° north, distant 2·13. The mention of the comet having traversed Cygnus probably applies to that of 1533; at any rate the comet of 1532 could not have passed through that constellation.

THE SUN'S PARALLAX.—Mr. David Gill, writing from Madeira, on his voyage to the Cape of Good Hope, to take the direction of the Royal Observatory, as successor to Mr. Stone, states in a communication to the Royal Astronomical Society, that the reduction of the observations of Mars, made during his expedition to Ascension, in 1877, have been so far completed that he is able to give the resulting solar parallax. He presents values, differing little *inter se*, deduced from various combinations of the observations and, as the definite figure, 8″·78, which being interpreted with the aid of Col. Clarke's last determination of the earth's equatorial semi-diameter, implies that the mean distance of the earth from the sun is 93,101,000 miles. This is a smaller parallax than perhaps was generally looked for, though not differing materially from several values which have been worked out recently.

METEOROLOGICAL REGISTERS[1]

THERE is now scarcely a meteorological observatory which is not provided with registering instruments. The number of these is already considerable,

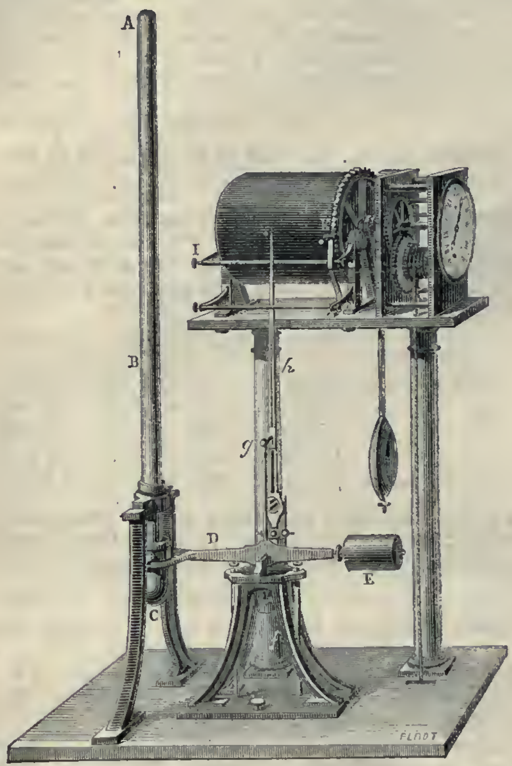

FIG. 1.—Registering Barometer.

and the methods of their construction are almost as numerous. At the observatory of Montsouris I have preferred continuous registration to registration by points, and the tracings effected by a fine metallic point on glazed paper blackened with smoke to the use of the pencil or to the *gaufrage* by pressure or by shock.

The barograph of Montsouris is a barometer-balance devised by P. Cecci, and latterly adopted by P. Secchi. The barometric tube A B (Fig. 1) is of iron, of 3 centimetres internal diameter, and of the same calibre throughout its length. It is fixed, and has, at its lower extremity, a cylindrical plunger, the full section of which is equal to the vacuum section of the barometric tube. The cistern, C, is of steel, and suspended to one end of the beam of a balance, D, the other end of which carries a counterpoise. The centre of gravity of the weighted beam coincides, as nearly as possible, with the central knife-edge, so as to render the equilibrium indifferent. Hence it results that when, in consequence of a rise of the barometer, a part of the mercury rises from the cistern into the tube, the former, thus rendered lighter, tends to rise, with the effect of introducing into the mercury of the cistern a greater length of the cylindrical plunger. Equilibrium is only re-established when (the volume of mercury displaced by the plunger being equal to that which corresponds in the tube to the increase in height of the barometric column) the level of mercury in the cistern returns to its constant point, and when, consequently, the apparent weight of that cistern has resumed its fixed value. The needle, *h*, of the beam of the balance marks its displacements on the surface of the blackened cylinder, K. It only remains to read the indications. To do this as accurately as possible, the support of the cylinder carries an electro-magnet, the armature of which is provided with an arm bearing a metallic point.[1] In ordinary weather this point is fixed, and traces on the cylinder a datum-line from which the ordinates of the barometric curve are measured; but every hour the electro-magnet is acted on by a clock marking the time on all the registers; the point departs momentarily from the line, and makes a clear stroke, which is reproduced at the same instant on the other cylinders. At the end of each week the cylinder is taken away, to be replaced by another kept ready, and is placed on the reading apparatus.

This apparatus (Fig. 2) consists of a horizontal steel bench, *f g*, provided on its upper surface with two columns, *h h'*, intended to support the axis of the cylinder, and on a vertical stand with two microscopes, which may be moved either separately or together in a horizontal direction. By means of an endless screw a movement of rotation on its axis may be communicated to the cylinder for the purpose of presenting successively to the microscopes the various faces of the cylinder. The microscope *b* is always pointed on the datum-line, and it is to follow this line in its accidental displacements, that the two microscopes may be moved together by the action of an adjusting screw. The microscope which points to the traced line carries at its focus two crossed threads, one horizontal and the other vertical. At each hourly reading one of the horizontal tracings on the datum-line is brought under the horizontal thread of the microscope. But, as the barometric curve often presents inflexions of which it is useful to note the exact time, the critical point of this curve being brought under the movable microscope *a*, a second horizontal thread, movable by a micrometric screw, serves to measure the distance of this point from the hourly mark immediately preceding.

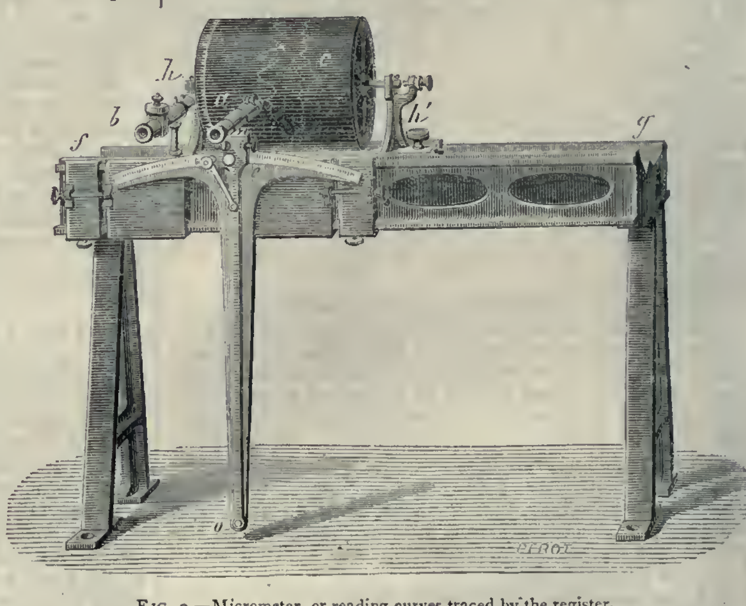

FIG. 2.—Micrometer or reading curves traced by the register.

The microscope *a* is supported at the extremity of an arm of a lever the length of which is equal to that of the

[1] Paper by M. Marié-Davy, *Journal de Physique*, April, 1879.

[1] This electro-magnet, which is seen in the thermograph (Fig. 3), is not shown in Fig. 1.

barometric needle; it describes, consequently, an arc of a circle of the same radius as the point of the register. This second microscope has a cross of threads like the first, but without a movable thread. The first microscope being pointed to an hourly sign, the axis of the second is directed to the corresponding point of the curve. The sine of the angle of position of its lever, multiplied by a

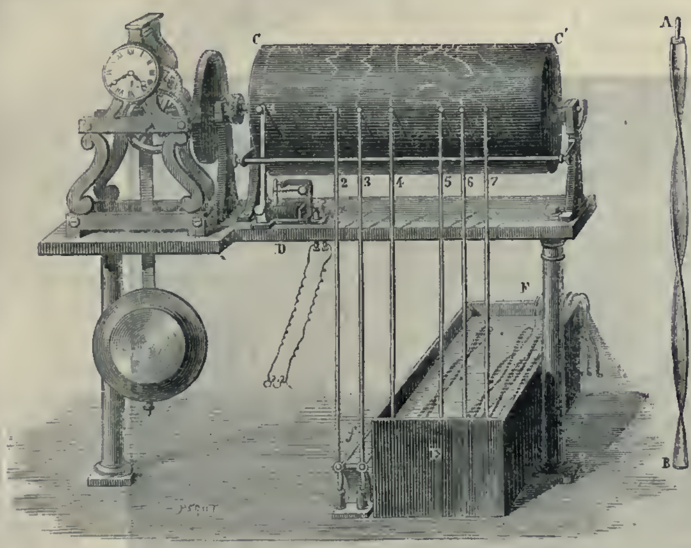

FIG. 3.—Thermograph.

constant factor and increased by a number equally constant, gives the height of the barometer at the moment selected. When the reading of the curve is made and verified, the sheet of blackened paper is taken off the cylinder and soaked in a weak solution of gum-lac or of copal in alcohol. By this means the smoked sheet is "fixed," and thereafter put in a portfolio.

The feeblest barometric variations are thus shown with

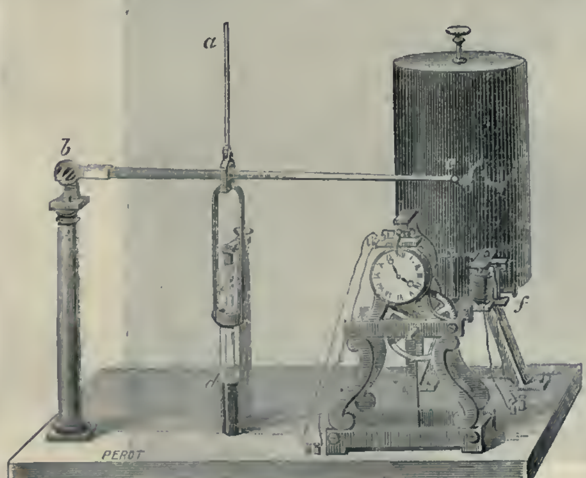

FIG. 4.—Register of the Atmograph.

great fidelity, and by examination of the curves we readily recognise the influence which the dynamical state of the atmosphere exercises in increasing or diminishing the weight of its pressure on the ground. It should be added that the uniformity of the calibre of the barometric tube annuls almost completely the action of temperature on the indications of the instrument.

The thermographs act in an analogous way, except that the motor is here formed by a Bourdon tube of hammer-hardened copper, with a very elongated elliptical section, and twisted into a sort of spiral, the thread of the spire varying from 2 to 3 centimetres, according to the purpose for which it is intended. A B (Fig. 3) represents one of these tubes, forming a little more than one spiral. This tube is exactly filled with alcohol, and closed at its two ends. The expansion of the alcohol compels it to untwist; but in order that its elasticity may be preserved, the internal pressure, corresponding to the highest temperatures to be reached, should not exceed 8 or 9 atmospheres. This pressure is all the greater in proportion as the thread of the spire is short. The twisted tube is fixed by one of its ends, the other free extremity bears the needle which gives the indications. At Montsouris this needle is 5 centimetres long, as is also that of the barometer. The process of reading the curves is thus exactly the same for all the needle registers. The new thermograph of Montsouris Observatory contains seven needles acting on the same cylinder. The first needle (No. 1, Fig. 3) belongs to the electro-magnet which traces the datum-line, and the hourly signs; needles 2 and 3 belong to the psychrometer; needles 4 and 5 record the temperature of the surface of ground exposed to the air without shelter; needles 6 and 7 correspond to the actinometer.

The psychrometer is formed of two twisted tubes placed outside on the north face of the wooden kiosk, which shelters the cylinder, and perpendicular to that face. Their furthest extremity is fixed, the other is prolonged through the wall of the kiosk by a stem of copper carrying the indicating needle. One of the twisted tubes is uncovered, and forms the dry thermometer; the other is covered with cambric, and kept moist by means of cotton-wicks dipped in small glass cups, connected with a Mariotte flask placed in the kiosk by means of a long and fine tube of caoutchouc. An instrument of this kind has been in use for fifteen months at Montsouris; its action is regular, and its sensibility very great.

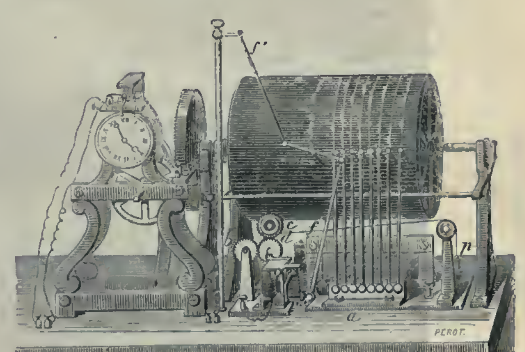

FIG. 5.—Anemograph.

The earth-thermometer is composed of two parts:—A thermometric reservoir of black copper is placed on the surface of a mass of vegetable mould, the top of which is flush with the platform of the roof of the kiosk; this reservoir communicates by a capillary tube of copper with a twisted tube placed in the kiosk under the cylinder of the register. When the temperature of the ground rises, a portion of the alcohol passes from the upper reservoir into the twisted tube, the pressure increases and the tube untwists; but the twisted tube itself and its capillary tube of

copper, are themselves acted on by the variable temperatures which complicate the results. A second twisted tube, similar to the first, provided with its capillary tube, serves to give the necessary corrections. The two twisted tubes are arranged parallel to each other in a trough, E F, filled with glycerinated water; the two capillary tubes are soldered to each other throughout their length. The two needles trace two curves, one very slightly sinuous, the other very undulating; the difference of their ordinates is measured. We thus obtain the temperatures of ground exposed to the sun during day, to nocturnal radiation during night, to rain and to evaporation.

The actinometer is also composed of two twisted tubes resting parallel to each other in the above-mentioned trough, E F, and of two capillary tubes. To each of these tubes corresponds a reservoir placed at the top of the roof of the kiosk, and inclosed in an envelope of glass on which a dry vacuum has been made. One of the reser-

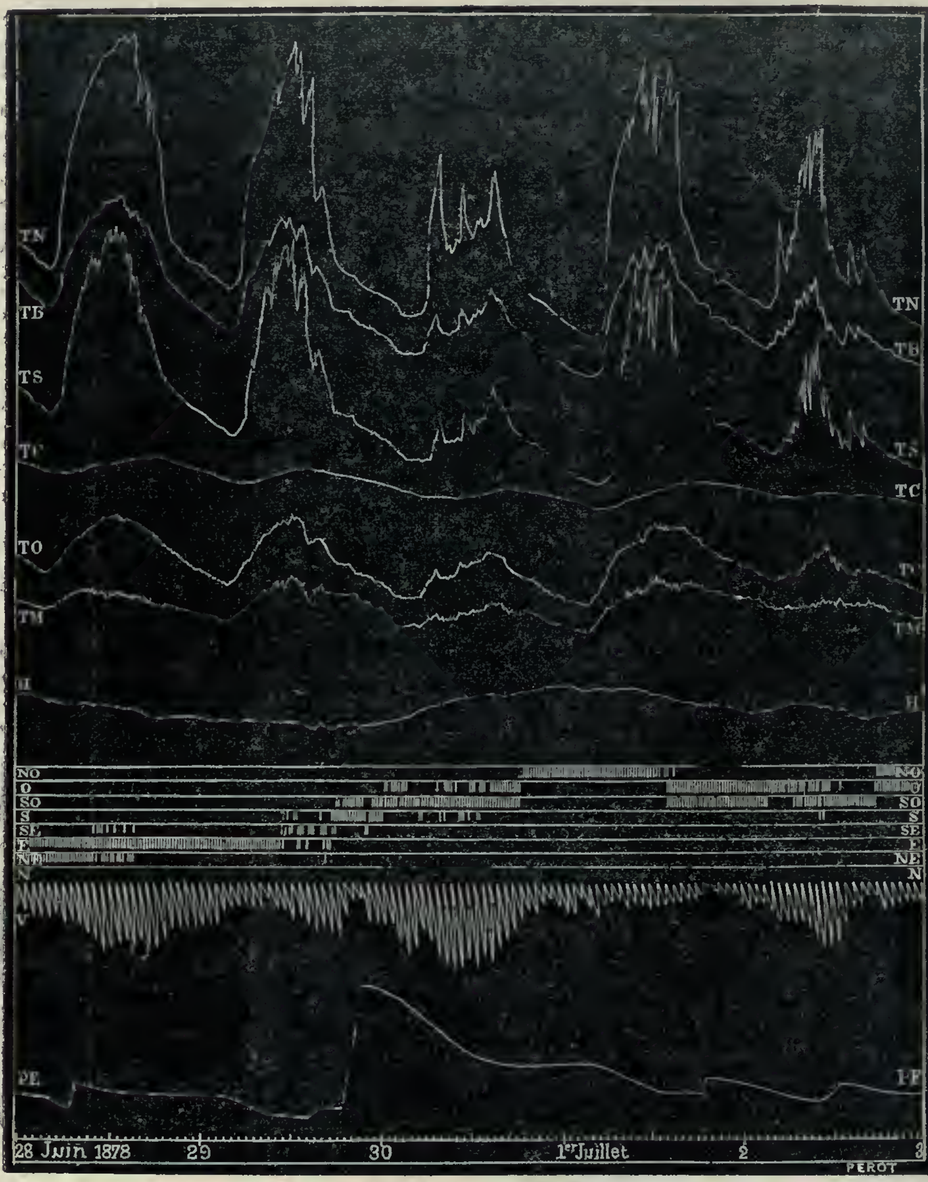

FIG. 6.—Specimen of curves made by the registers of Montsouris.

voirs is silvered, the other is blackened. Placed symmetrically at a little distance from each other, and far from any shelter, they give the same indications during the night; but during the day the black thermometer registers higher than the white one. The differences of the ordinates of the curves traced by the two needles serve to measure the actinic degree. Every cloud which passes over the sun gives rise to a rapid and considerable lowering of the temperatures of the white and black thermometers, and of that on the surface of the ground.

The atmograph is a third registering instrument intended to mark the variations of weight of a mass of earth whose surface is flush with the summit of the platform of the roof of the kiosk, and is exposed to the sun, to evaporation, rain, snow, and dew. At a little distance is the registering rain-gauge. The comparison of the

two curves shows what becomes of the water which falls on the naked earth, without vegetation, distinguishing between what returns to the atmosphere by evaporation, and what penetrates the subsoil which is permeable or drained. Another atmograph gives similar indications for a soil covered with various plants; but the latter being sheltered from the wind, ought to be moistened according as is necessary. Fig. 4 represents only the register of the atmograph. *a* is the lower part of the stem which is suspended to the extremity of the arm of the balance, in which is placed the mass of earth. A second lever arm, *b c*, follows and amplifies the movements of that stem which it inscribes on the vertical cylinder covered with paper blackened with smoke. This same stem bears a glass test-tube, *d*, containing mercury, in which is a fixed glass tube *e*. The diameter of this stem is so calculated that the point *c* traverses 100 millimetres for each millimetre of water gained or lost by the mass of earth. In calm weather we may thus appreciate the $\frac{2}{100}$th of a millimetre; but when the atmosphere is disturbed, the vertical components of the wind cause the needle to oscillate, thus interfering with the precision of the readings.

The anemograph (Fig. 5) gives us, at once, the direction of the wind and its mean rate per hour. Eight electro-magnets communicating electrically with the sectors arranged on the vane according to the eight principal points of the compass, can, by acting singly or two and two, record the winds for sixteen directions, which may be regarded to be sufficient for the wants of meteorology. A ninth electro-magnet is acted on each time that the Robinson drum shows a length of one kilometre traversed by the wind. The toothed wheel *b* then moves one division, and its movement is transmitted by the satellite wheel *d* to a third toothed wheel, *c*, on the axis of which is rolled a thread, *cp*. The point which marks the velocity then advances 1 mm. towards the left. This effect is produced during one hour for each kilometre traversed by the wind; but at the end of each hour the needle of the clock establishes an electric contact; the satellite wheel, *d*, is lowered; the wheel, *c*, becomes free; and the weight, *p*, restores the metallic point to its starting-place.

Fig. 6 presents a specimen of the curves traced by the registers from June 28 to July 3, 1878, reduced to one-third of their natural size. Beginning at the top, we find first the two curves, T N and T B, which together furnish the actinometric data; T N is the curve of the black thermometer, T B that of the silvered. The two following curves, T S and T C, give the temperature of the surface of the ground without shade; T S corresponds to the ground thermometer; T C gives the correction to be made in the ordinates of the first. The two curves, T O and T M, are those of the dry and wet thermometers; besides the temperature of the air in the shade, they give its hygrometric degree and the elastic force of its vapour. H is the curve of barometric pressure.

Underneath are eight straight lines corresponding to the eight principal directions of the wind; the vertical lines which rest on them indicate the directions in which the wind has blown. Further down are shown the velocity, V, of the wind in kilometres per hour.

The last curve, P E, is made by the atmometer; the increase in a vertical direction of this curve marks rain; the decrease marks evaporation. Notwithstanding the frequent and at one time very copious rains, the earth, on July 3, had very nearly resumed its weight of June 28. Finally, the last line is the datum-line on which the hours of the day are marked.

GERMAN PHYSIOLOGICAL CHEMISTRY[1]

As our general knowledge of nature increases, the possibility of individual knowledge decreases; the variety of discovery, the immense number of investigators, and the innumerable details which they accumulate in their respective branches of science, preclude the possibility of a modern "admirable Crichton." Werner's sigh, "True I know much, but yet I would know all," has been long acknowledged as an aspiration incapable of fulfilment, even supposing him to limit his desire of knowledge within the bounds of what is already known. To know "something of everything, and everything of something," is all that can be hoped for; day by day each science advances with such rapid strides, that one brain is incapable of grasping more than the general principles of one science; and any man who aims at enlarging the domain of science by fresh discovery, must content himself with confining his attention to a small corner, and by patient industry and indomitable perseverance seek to elicit some new facts.

[1] From Hoppe-Seyler's "Zeitschrift über physiologische Chemie."

Such, expressed in general terms, is the drift of the preface to Hoppe-Seyler's "Zeitschrift für physiologische Chemie." It seldom happens—unfortunately too seldom in this country—that medical men have more than a smattering of chemistry. A very low standard of chemistry is required for a medical degree, comprising a superficial knowledge of inorganic chemistry, chiefly of the non-metals; the merest smattering of organic chemistry, and ability sufficient to detect the acid and base in simple salts—such are the qualifications in chemistry necessary for graduation in medicine. When the student, following out the prescribed course, comes to attend lectures on physiology, and hears—almost always for the first time—the names of the various principles contained in the animal fluids, in the brain, in the liver, and in the muscular tissue, they fail to convey any definite idea to his mind, and he is utterly unable to comprehend, or even to form an idea of the reactions which take place in the animal organism. In Germany this state of things has been recognised in many universities, and special professors of physiological or animal chemistry have been appointed; these professors are not merely teachers, but are engaged in the active extension of their branch of science; and it is to facilitate the interchange of ideas between them, and to afford a medium in which the results of their investigations may be brought together, that Hoppe-Seyler has undertaken the editorship of this journal.

One noticeable feature of the investigations of German physiological chemists at present, is the attention devoted to ascertaining the changes which food undergoes in passing through the system. At least six memoirs on the subject are to be found in the nine published numbers of the journal, comprising the work of a year and a half. The methods and results of these experiments are worthy of a short description.

The food which we eat consists for the most part of carbon, hydrogen, and nitrogen; all food, however, does not contain nitrogen; starch, sugar, and fat are devoid of that element. The carbon and hydrogen, after being absorbed by the tissues, and performing work, are cast off as waste material, partly by the lungs, in the form of carbonic acid and water-vapour, and also, to a much smaller extent, in the urine. An almost inappreciable amount of nitrogen escapes by the lungs; by far the largest portion passes into the urine in combination with hydrogen and carbon, in the form of urea—a white crystalline body. Now this substance, urea, possesses a chemical, as well as a physiological interest. It was formerly supposed that all chemical compounds could be divided into two grand classes: inorganic bodies, such as could be prepared from purely mineral matter; and organic bodies, those existing only in a living organism, or obtained from these compounds by a process of decomposition. It was, therefore, imagined that an insurmountable barrier separated the two classes. Urea was ranked as an organic substance, for it had never been obtained except from the organism, till Prof. Wöhler, of

Göttingen, succeeded in preparing it from material of purely mineral origin. This process was to heat ammonium cyanate, $NH_4.CNO$, when, without decomposition, a new body was formed, possessing all the properties of, and undistinguishable from, urea. It has since been discovered that urea is very closely connected with the carbonates of ammonium, that, in fact, it is simply carbonate of ammonium minus water. Now it appears probable that urea is formed in the organism either from ammonium cyanate or from ammonium carbonate, and the question which Prof. Salowski, of Berlin, has tried to answer is: By which process is it formed? (vol. i. p. 1). As there is a general resemblance between all nitrogenous food, inasmuch as it contains albumen itself, or principles closely allied to albumen—among others, myosine, vitelline, serum-globuline (which form the subject of an article by Th. Weyl [vol. i. p. 72]); and moreover, as cyanic acid, carbonic acid, and ammonia, are products of decomposition of albumen, the question is an open one.

Every one knows the old plan of detecting the filcher of coin from a till, by placing a secret mark on a number of the coins, and so making their identity unmistakable. The plan adopted by Prof. Salowski is somewhat similar, though the simile is not quite applicable. There is a method of putting a private mark on cyanic acid and on ammonia, by using compounds containing more carbon in the former case, and by employing a substituted ammonia in the latter, that is, a substance possessing in the main the properties of ammonia, but capable of recognition afterwards. But as neither ammonia nor its salts are normal constituents of food, it was necessary to prove that by giving ammonia, a compound of nitrogen and hydrogen, along with food, the amount of urea in the urine is increased. Direct experiments on rabbits proved the point. After feeding them on a diet of potatoes containing a known amount of nitrogen, the amount of urea eliminated was augmented by addition of salts of ammonia to that diet. Now by introducing ammonia to form carbonate of ammonium, two atoms of nitrogen are introduced; and if that ammonia were "marked" the resulting urea would be "marked" also, and would contain two atoms of "marked" nitrogen. But, on the other hand, if the reaction takes place between cyanic acid (a body containing one atom of nitrogen itself) and ammonia, only one atom of nitrogen would be derived from the introduced ammonia, and if that ammonia could be afterwards identified, the urea into which it is resolved should contain only one atom of marked nitrogen.

In chemical language, let ethylamine be substituted for ammonia; in the first instance the equation should be—

$$C_2H_5NH_2 + HCNO = CO \left\{ \begin{array}{l} NH_2 \\ NH.C_2H_5 \end{array} \right. ;$$

and in the second—

$$CO(C_2H_5 . NH_2)_2 - 2H_2O = CO(NHC_2H_5)_2.$$

The former hypothesis was found to be true; only one nitrogen atom in the urea bore the mark, and the reaction is proved to take place by cyanic acid and ammonia combining, and then altering into urea, a body of the same composition but different properties, otherwise called an isomeride.

In spite, however, of this apparently convincing experiment, Prof. Salowski regards it as improbable that urea is actually formed by the reaction between ammonia and cyanic acid, unless, indeed, ammonia be supplied directly to the organism; he takes the view that under normal circumstances the urea is derived solely from cyanic acid assimilating water and evolving ammonia thus:—

$$2CNOH + H_2O = CO(NH_2)_2 + CO_2.$$

This would account for the increase of urea under a diet containing ammonia.

Dr. E. Baumann (vol. i. p. 60) contributes a paper announcing the discovery of phenol, or carbolic acid, in urine, and remarks that it is curious to observe a substance regarded as a preventive of fermentation generated, although in extremely small quantity, by fermentation. He also noticed the appearance of a nearly allied body, indicane, which, on allowing the urine to stand, changed into indigo, the well-known dye.

The colouring matter of the blood forms the subject of a series of contributions from the pen of the editor, Prof. Hoppe-Seyler (vol. i. pp. 121, ii. 149). Every one has noticed the fact that blood from an artery has a brighter red colour than that from a vein; the cause of this is that arterial blood is pumped by the heart from the lungs, where it has received a supply of oxygen from the air, into the arteries, which distribute it through the body. During its progress this oxygen is gradually used in oxidising waste matter and in converting the spent carbonaceous substances, which have fulfilled their purpose, into carbonic acid. The blood takes up this carbonic acid, and in doing so its colour becomes darker. The bright red principle of the blood is named oxyhæmoglobine, and after it has turned dark it has changed to hæmoglobine. Both of these substances can be separated from blood by appropriate processes. When placed in a tube and viewed through a spectroscope, oxyhæmoglobine exhibits two dark bands, whereas hæmoglobine shows only one band, occupying a position nearly between that of the two bands of oxyhæmoglobine, but slightly overlapping the one at the red end of the spectrum. These two substances can thus be easily distinguished from each other, and as the smallest trace of oxygen converts hæmoglobine into oxyhæmoglobine, the spectrum of which is easily recognised, even in presence of the other, a dilute solution of the former is a very delicate test for the presence of oxygen in liquids; so delicate, indeed, that one cubic millimeter of oxygen, or about as much as would occupy the space of a pin-head, can be detected.

It is of course evident that, as decay, and consequently removal of used-up material proceeds throughout the whole body, it is impossible to obtain blood, either wholly charged with oxygen or wholly free from it. Yet to be able to detect oxygen in such minute quantity, it is necessary to procure hæmoglobine absolutely free from oxygen. Hoppe-Seyler effects this by exposing the colouring-matter of blood to a putrefying medium; the small living organisms consume the oxygen that it contains, and reduce it to hæmoglobine. He remarks, *en passant*, that the colouring-matter of the blood withstands putrefaction perfectly, as well as the action of a special ferment found in the pancreas, which in this respect resembles bacteria, the living organisms in ordinary putrefying media.

This very delicate test for oxygen has been applied to various animal secretions. Saliva from the parotid and submaxillary glands, as might be expected from its proximity to external air, contains oxygen, but neither gall nor urine contain any, owing to the presence of easily oxidised substances named bilirubine and hydrobilirubine, by which any free oxygen is consumed.

It is not uncommon to hear of deaths caused by sleeping in an apartment in which there is a charcoal-stove. This is owing to the poisonous qualities of carbonic oxide gas produced by the combustion of the charcoal, and the effect is not improbably due to the formation of a compound between the hæmoglobine of the blood and the gas. Blood, when charged with carbonic oxide, acquires an almost vermilion-red colour. It also gives a characteristic spectrum, and its examination shows with certainty the cause of death. Hoppe-Seyler has noticed that, like oxyhæmoglobine, the compound of carbonic oxide with hæmoglobine is not destroyed by putrefaction, and hence blood taken from the veins long after death reveals the carbonic oxide spectrum, if death has resulted from charcoal-poisoning.

M. Dionys Szabó has made the character of the acid in gastric juice a subject of research (vol. i. p. 140), and has ascertained that it consists of both hydrochloric acid and lactic acid, analogous to that produced by the souring of milk. As hydrochloric acid is the more powerful corrosive and solvent agent, it is natural to expect it to be present in larger quantity than lactic acid in the stomach of the dog, which requires it to bring fragments of bone, &c., into solution. In certain dyspeptic cases hydrochloric acid is wanting, hence, probably, the dyspepsia, owing to lactic acid alone not being sufficient to bring the food into solution. It is probable that the lactic acid is produced from the albuminous constituents of food by oxidation, and that it acts on the salt which we take with our food, forming lactate of sodium, and liberating hydrochloric acid. Chemical decompositions of this nature, the converse of what happens in laboratory experiments, appear to be greatly favoured by dialysis through colloidal membranes, such as the walls of the ducts of the mucous membrane of the stomach.

Prof. Richard Maly (vol. i. p. 174) has made an attempt to explain the phenomenon of inverse chemical reactions, occurring under the influence of diffusion, with regard to the formation of hydrochloric acid. Prof. Graham, in his well-known researches on diffusion, showed that hydrochloric acid is the most diffusible of all liquids; that if a jar be filled with it, and carefully immersed in water, taking care not to mix the acid with the water, more hydrochloric acid escapes in a given time than is the case, under similar circumstances, with any other liquid. Now it is an ascertained fact that a weak acid can replace a strong one to a small extent, provided the weak acid is present in large quantity compared with the strong one. This replacement proceeds to a given point, when balance sets in, and the reaction goes no further, owing to the strong acid being liberated in such amount as to check any further decomposition, provided no disturbance takes place. But in the case of lactic and hydrochloric acids in the stomach, disturbance does take place, owing to the more rapid diffusibility of hydrochloric acid through the walls of the ducts. The hydrochloric acid is constantly being removed as it is formed, and the sodium chloride, or common salt, is continually in process of decomposition by the lactic acid. Hence the presence of hydrochloric acid in gastric juice. This decomposition is also effected by what is generally called "neutral sodium phosphate," which, although it has a faint alkaline reaction on litmus paper, yet, in a chemical point of view, is an acid substance, for it still contains hydrogen replaceable by a metal.

Dr. O. Lassar (vol. i. p. 165) contributes a paper on irrespirable gases. Every one who has visited a vitriol work knows the insufferable feeling of choking produced by the fumes of the evaporation-chamber, and even those who have not had that opportunity must occasionally have experienced the disagreeable sensation of breathing the fumes of burning sulphur from a sulphur match. This choking sensation seems not to be felt by animals; it is due to spasm in the glottis and involuntary contraction of the vocal chords. The object of Dr. Lassar's experiments was to ascertain whether such acid fumes are absorbed by the lungs, conveyed into the blood, and passed out by the urine. For this purpose he exposed rabbits and dogs to the dense fumes of sulphuric acid for more than an hour at a time, and examined the urine carefully for that acid. It was invariably absent, showing that the acid is not absorbed by the lungs. It was curious to remark that on exposure of an animal to nitric acid vapour of such strength that the hair, and even the membrane of the lungs, turned yellow, the animal did not suffer in health, and that the only effect of acid fumes in air is to diminish the proportion of oxygen. This explains what has often been wondered at—that workmen in the chlorine chambers and sulphuric acid evaporating-chambers are not injuriously affected by the acid fumes.

WILLIAM RAMSAY

GEOGRAPHICAL NOTES

THE special committee appointed by the International Meteorological Congress at Rome for the promotion of expeditions to the Arctic seas charged with making synchronous meteorological and magnetic observations, will meet at Hamburg on October 1 next, in order to arrange details and to discuss the means of arriving at the object aimed at. Preliminary steps in this direction have, as our readers are doubtless aware, been taken by Count Wilczek and Lieut. Weyprecht.

ON August 7 next a century will have elapsed since Karl Ritter, unquestionably the greatest geographer of his time, was born at Quedlinburg.

IN the last issue of the *Colonies and India* the attention of members of the Alpine Club is directed to the mountain peaks of the West Indies. In the Blue Mountains of Jamaica, for instance, views can be obtained which cannot be surpassed in the world. Many of these mountains have been, as yet, untrodden by the foot of man, and they offer a wide field to the student of natural history as well as the practical explorer. In the Island of Dominica, again, there are opportunities for exploring mountains which are hardly, if at all, known. An expedition under two Englishmen has lately scaled for the first time one of the peaks, known as Morne Trois Pitons, situated to the north of Roseau. The heights of these peaks are 4,528, 4,552, and 2,672 feet respectively. The foot of the centre *piton* was found to be at an elevation of about 1,800 feet. For a considerable distance the party were able to follow a wild-pig track, but they had to leave this and cut their way through dense vegetation and scrub. On reaching the summit they found it to be nearly flat, and covered with impenetrable vegetation. This curious plateau was estimated to be about ten acres in extent.

THE new number of the Belgian Geographical Society's *Bulletin* publishes reports from M. Cambier and Dr. Dutrieux on the march of the first Belgian African expedition from Mpwapwa to Tabora, in Unyanyembe. These are accompanied by a sketch-map of the country between the East Coast and Lake Tanganyika, on which the route of the expedition is laid down.

A GOOD harbour is stated to have been discovered near Point Parker, in the Gulf of Carpentaria, which will probably be of service in the development of that part of Australia.

THE Coreans are as little given to leaving their own country as the Japanese used to be, but we learn from a Shanghai contemporary that there appears to be a little colony of them forming in the neighbourhood of Chinkiang, for, in addition to the usual *ginseng* traders, there are now there several well-dressed Coreans having the appearance of the better class of officials. They wear slate-coloured garments as a sign of mourning for the Queen.

THE new number of *Le Globe* contains M. Veniukof's account of geographical work in Asiatic Russia during 1878, and a paper on the Sahara.

THE last *Bulletin* of the Société de Géographie Commerciale of Bordeaux has a long note on French establishments in India, which will be found useful in supplying information on a subject respecting which the world at large knows but little.

THE just published number of *Les Annales de l'Extrême Orient* contains the continuation of Dr. Harmand's notes on Khmer monuments, and of the Marquis de Croizier's essays on Indo-China, based on Dr. Bastian's investigations.

NOTES

PROF. TACCHINI has been appointed Director of the Central Office of Meteorology and of the Observatory of the Collegio Romano.

WE are requested to announce that during the months of August and September, the apartments of the Geological Society will be closed on Saturdays at 2 o'clock in the afternoon.

WE are glad to hear that there is a likelihood of the late Prof. Rankine's papers being republished in a collected form. Mr. W. J. Millar, of Glasgow, has been asked to act as editor, and is at present drawing np a list of papers which it might be advisable to reprint.

THE French Association for the Advancement of Science will hold its next session at Montpellier, as we announced some time ago. One of the two lectures will be on the "Electric Light," of which there will be a splendid display. The meeting of the Association will take place on August 28, so that the great heat will be no obstacle to the excursions, which will be attractive, as every effort will be made to take advantage of the exceptional position of the city. Montpellier being one of the oldest universities in the world, a number of historical relics will be exhibited for the first time to strangers, of high interest in the development of science.

THE meeting of the Swiss Association of Naturalists will take place at St. Gallen on August 10-12 next. The committee invites foreign naturalists to attend the meeting. The detailed programme may be had upon application to the secretary, Herr Stein, at St. Gallen.

DURING the last days of June shocks of earthquake of moderate intensity were felt on the south-east side of Mount Etna, particularly in the vicinity of the little town of Zafferana. The great crater at the time was sending forth a mighty thick black column of smoke. On the southern slope of the mountain the earthworks for the erection of the great astronomical observatory, for which Prof. Tacchini drew the plans, have been begun. The observatory will stand at an elevation of 3,000 metres above the sea; the largest telescope will measnre 33 centimetres in diameter. The Commission appointed by the Italian Government to study the phenomena accompanying the recent eruption, hav proposed the establishment of a Cabinet for Vulcanology, of which Prof. O. Silvestri is to be the director.

THREE violent shocks of earthquake occurred at Athens on July 3 at 4.15 P.M. The centre of the oscillations seems to have been at Xylokastron, near Corinth. On Mount Parnassus and at Thebes the phenomenon was also noticed. At Athens another shock was felt on the 6th shortly after midnight.

MR. W. LANT CARPENTER describes in the *Bristol Mercury* a visit he recently paid to Mr. Edison's laboratory at Menlo Park. The laboratory, workshops, &c., he states, as well as some isolated buildings for delicate electrical measurements, are spread over an acre of ground, railed in, admission to which is only given to privileged visitors. While waiting for Mr. Edison, Mr. Carpenter was conducted by a messenger through all the physical, chemical, and private experimenting laboratories, and then through the workshops, the machinery of which is driven by a beautiful, high-pressure, eighty-horse engine, also used to drive the electric-light machinery, most of which is in the same shop. About a dozen workmen were engaged, some in electrical test measnrements, &c., but chiefly in manufacturing Mr. Edison's latest form of telephone, constructed for the electric and hygrometric conditions of our English atmosphere. Mr. Edison admitted that he was not doing very much at present at the problem of domestic electric lighting. He appeared to consider the question of its economical subdivision a solved problem (he had sixteen lamps in the workshop, each with its small coil of platinum wire, in a glass globe, three to four inches diameter), and was now giving attention to the details of lamp construction. This new form of lamp is to be a minute cylinder of compressed pure zircon, a rare earth allied to magnesia, which is to be heated to whiteness by the surrounding coil of platinoiridium wire. A chemist was engaged in purifying zircon for this purpose. The newest thing in the shop was a dynamometer, the last and best of several invented by Mr. Edison, with the result of which he was perfectly satisfied, and he stated that with this instrument he had been able to show that, after deducting the necessary amount for friction in the machinery, more than 95 per cent. of the mechanical force employed was obtained in the form of light. Mr. Carpenter informs us that in consequence of a circular addressed by Mr. Edison to miners in Colorado (whence Mr. Carpenter has just returned) and elsewhere, platinum is being widely discovered in these districts, now attention is directed to it.

THE summer meeting of the Institution of Mechanical Engineers will be held in Glasgow, by the invitation of the Institution of Engineers and Shipbuilders in Scotland, commencing Tuesday, August 5. The following papers will be read and discussed:—"On the Pneumatic Marine Governor," by Mr. W. J. Dunlop, of Port Glasgow.—"On the 'Velometer' Governor," by Mr. F. W. Durham, of London.—"On the Maintenance of Constant Pressure in Water Service Pipes," by Mr. Stephen Alley, of Glasgow.—"On the Barton Water Regulator, or Reducing Valve," by Mr. W. H. Thomas, of London.—"On the Forging of Crank Shafts," by Mr. W. L. E. McLean, of Glasgow.—"On Water-pressure Engines with Variable Stroke," by Mr. John Hastie, of Greenock.—"On the Working of Traction Engines in India," by Mr. R. E. B. Crompton, of London.—"On the Construction and Working of a Vertical Action Steam Dredger," by Mr. R. B. Buckley, of the Public Works Department, Bengal.—"On Plate-rolling Machinery," by Mr. Edward Hutchinson, of Darlington.—"On Barton and West's Water Meter," by Mr. W. H. Thomas, of London. A number of interesting visits and excursions have been arranged.

WE are requested by the Committee of the Sunday Society to publish the following:—"Through the kindness of Sir Coutts Lindsay, the proprietor and director of the Grosvenor Gallery, the members of the Sunday Society have to-day (Sunday, July 27) been favoured with admission to the Summer Exhibition, between the hours of 6 and 8.30 P.M., and nearly 500 have availed themselves of the privilege. Next Sunday the Gallery will be opened to the public, free by tickets, which will be issued by the Society to all persons making written application and sending stamped and addressed envelope, for reply, to the Honorary Secretary, 19, Charing Cross, S.W. A special catalogue has been published by the Society, price 4*d.*; this must be obtained before Sunday, as no catalogues will then be on sale."

AN exhibition somewhat similar to the one we described at the Royal Aquarium, but on a larger scale, of plans, diagrams, models, apparatus, and all appliances illustrative of the various subjects that have to be considered in planning water-supplies, and the domestic arrangements for making them in the best way available, is to be held at the Alexandra Palace. The Exhibition will be arranged in fifteen section as follows:—Section I. Physics and Chemistry; Section II. Rainfall, &c.; Section III. Rivers; Section IV. Geology and Hydro-Geology; Section V. Waterworks; Section VI. Distribution of Water; Section VII. Statistics; Section VIII. Water Examination; Section IX. Filtration; Section X. Hardness; Section XI. Disease; Section XII. Antiquarian; Section XIII. Pollution; Section XIV.

Literature; Section XV. Few people really know anything of the various considerations that are involved in selecting and maintaining a "pure" and sufficient water-supply, and the spread of some of the knowledge that has been obtained may help to remove many of the prejudices against improvements, and may show that low water-rates are perhaps not the only points that ratepayers should regard. Sections X. and XI. especially refer to matters of general interest too often overlooked. It is hoped that a permanent museum, to be located somewhere in London, may result from this exhibition. All communications for the Committee should be made to Mr. A. T. Atchison, 34, Great George Street, S.W., and applications for space and for information respecting the exhibition should be made to Mr. W. H. Jones, Manager, Alexandra Palace, N.

THE new (German) Geological Society of Metz has just published its first *Jahresbericht* (for 1878). Apart from the usual report of proceedings at the meetings, the publication contain an interesting paper by Capt. Schultzen on the old Roman aqueduct from Gorze to Metz.

THE death from apoplexy is announced of M. Louis Favre, the contractor for the St. Gothard Tunnel. He was 53 years of age, and had engaged in nine years to construct a tunnel nearly 15 kilomètres long through beds of granite, gneiss, and serpentine. Notwithstanding difficulties of all kinds, the work had been carried on interruptedly for six years, the estimate being so careful that there was no excess of outlay, and M. Favre expected in two years to complete the work.

WE have received from Mr. E. Paterson, of Bedford Court, Covent Garden, parts i. and ii. of an unusually well got up illustrated Catalogue of Electrical Apparatus manufactured by him. Not only is the Catalogue itself exceedingly full and drawn up with much intelligence, but in the second part some really useful practical information is given on the principles and fixing of electric signals, which, we daresay, will be welcome to many. We are sure many of our readers will find Mr. Paterson's Catalogue of considerable service.

THE Americans have stolen a march upon us in sanitary matters, as they have done in so many other things. In March of this year an Act passed the U.S. Congress organising a Board of Health to look after all matters relating to the public health, and to advise Congress what steps should be taken for the promotion of so all-important a matter. We have just received the first number of the weekly *National Board of Health Bulletin*, published by this body, who have 50,000 dollars appropriated to them for salaries and expenses. Besides mortality statistics the *Bulletin* contains a number of rules and regulations with respect to the sanitary condition of ships.

M. COULON, conservator of the Industrial Museum of Rouen, has discovered a new system for transforming sound into light, which phenomenon has been the subject of a lecture at the Salle des Capucines by M. Frank Geraldy with the Gower telephone. Two Geissler tubes are put in quick rotation on an axis. The Ruhmkorf coil of the first is worked by an ordinary interruptor and gives the deviation of a luminous cross. The interruptor of the second is replaced by a telephone. The figure presented by the second tube projects on the first one, which is coloured by uranoxide glass and exhibits the most rapid changes according to the height of the note delivered in the telephone-trumpet. The sensibility of the changes are startling and most interesting. An exhaustive lecture by M. Coulon will be given at Rouen in a few days, and the apparatus exhibited at the Palais de l'Industrie.

DR. MOESTA has discovered the remains of an oak forest at a depth of 7 feet or 8 feet, near Rotenburg. The number of well-preserved trunks is enormous; one of them is 18 mètres long and 1 mètre and a half in diameter. This bog oak will be used for carving.

THE twenty-fourth meeting of German and Austrian Apiculturists will be held at Prague on September 7-11, and will be accompanied by an international exhibition of living bees, and all products and apparatus connected with bee-culture.

THE second Congress of Austrian wine-growers will be held at Vienna on September 22-25, and will be accompanied by an exhibition of all products, apparatus, and implements connected with viticulture.

AT Roveredo a statue has been erected to the eminent philosopher and statesman, Antonio di Rosmini-Sarbati (born 1797, died 1855). The work was executed by a Florentine sculptor, and the material is Carrara marble. The statue is said to be an excellent likeness.

PHYLLOXERA is unfortunately making rapid progress in Savoy. Since July 1 no less than forty-two different vineyards in the cantons of Chambéry, Montmelard, Yenne, and Rochette have been attacked by the pernicious insect; the head-centre of the infection seems to be at Chambéry and at Montmelard.

HERR KARL RUSS, the eminent German ornithologist, is writing a new work on foreign domestic birds, in three volumes. Two are completed and part of the third has recently appeared. Herr Karl Rümpler, of Hanover, is the publisher.

THE Central School Depot publishes a clearly written and instructive penny tract—"A Few Interesting Facts about Light, simply Told, for Young People," by the Rev. F. J. C. Fenton. Mr. Fenton discards all technical terms, and conveys a wonderful amount of accurate elementary information in a few pages.

A JAPAN paper says that there is a prospect of a new coal mine being worked in Ishigari, in the island of Yezo, the resources of which are only now beginning to be gradually developed. Some foreign experts in the employ of the Kaitakushi, or Colonisation Department, which is doing good work in Yezo, have tested specimens of coal and found them to be of good quality and suitable for purposes of steam navigation. As the locality where the coal exists is at some distance from the coast, it is proposed to construct a railway from it to the sea-board, and a survey of the country for that purpose is now being proceeded with.

FROM a recent investigation of the electric arc by Professors Thomson and Houston (*Journ. of Frank. Inst.*) it appears that the relations between arc resistance and current strength and between current strength and illuminating power, are expressed by the following laws:—(1) In arcs of equal lengths the resistances are inversely proportional to the current strengths; (2) The illuminating power of an arc is approximately proportional to the current traversing it; (3) In arcs of equal length the total energy given out is proportional to the current strength.

INTELLIGENCE has been received from Ceylon that the examination of supposed pearl-oyster banks on the east coast has not resulted in the discovery of any deposits worth fishing. The oysters found, though of the pearl kind, contained no pearls. It is supposed that they had been washed by currents from deep-sea banks in the Bay of Bengal.

UNDER date of April 30, a correspondent of the *North China Herald* at Wladivostock, in Russian Manchuria, writes that, although the mountain tops were still covered with snow, the winter had at length come to an end, the ice in the harbour having on that day broken up and floated out to sea. The winter began in October and has been the severest known for many years. The bay was entirely covered with ice from two to three feet thick. Wladivostock is said to be improving, though slowly, and there are signs of an attempt at road-making.

THE *Japan Gazette* learns that as an encouragement to the producers of tea, silk, and cocoons, it has been resolved by the Government to hold an exhibition of these articles in the Machigwai-sho at Yokohama. Foreigners and native dealers are not to be allowed to exhibit, as the scheme is devised entirely for the benefit of producers and manufacturers.

GOLD-BEARING quartz has lately been discovered at Sarugoye in the Yamato district of Japan.

THE *Golos* reports the discovery in the district of Perejaslavl, Pultowa Government, of 370 flint arrow-heads, a number of bones of men and animals, fragments of earthenware, and bronze objects.

THE *Annual Report* of the Goole Scientific Society for 1878-9 records satisfactory progress. As the result of a rule admitting ladies, twenty-one have joined the society.

THE Hull Literary and Philosophical Society, to judge from the Report for 1878-9, seems to be doing a great variety of good work in their district by means of lectures, papers, classes, &c. The Society is in a flourishing condition as to members and funds, and has added, during the session, a Microscopical and a Geological Section.

THE additions to the Zoological Society's Gardens during the past week include two Red and Yellow Macaws (*Ara chloroptera*), a Red and Blue Macaw (*Ara macao*), a Blue and Yellow Macaw (*Ara ararauna*) from South America, a Common Trumpeter (*Psophia crepitans*) from Demerara, presented by Mr. Chas. Fricker; two Golden Eagles (*Aquila chrysaëtos*) from Scotland, presented by Mrs. A. H. Browne; a Geoffroy's Marmoset (*Midas geoffroii*) from Panama, purchased; a Stanley Crane (*Tetrapteryx paradisea*) from South Africa, received in exchange; a Bay Antelope (*Cephalophus dorsalis*) from West Africa, deposited; a Peacock Pheasant (*Polyplectron chinquis*), two Black-crested Cardinals (*Gubernatrix cristatella*), two Geoffroy's Doves (*Peristera geoffroii*), bred in the Gardens.

THE EOZÖON CANADENSE

WE have received the following communications on this subject:—

I shall be glad to be allowed to ask your readers to suspend their judgment in the matter of *Eozöon*, until the appearance of the *full and complete memoir*, based (I venture to say) upon investigations far more comprehensive than those of Prof. Moebius—upon which I am now engaged, in conjunction with my friend Prof. Dawson. But as the production of this memoir will necessarily be a work of considerable time, on account of the elaborate illustrations it will require, I would now offer the following brief remarks on that part of Prof. Moebius's discussion which relates to the so-called "canal-system."

Among the numerous beautiful figures which Prof. Moebius has given of *sections* of the "canal-system," there is not one which represents what I described and figured, when I last wrote on the subject (*Ann. of Nat. Hist.*, June, 1874, plate xix.), as "what appears to be the typical mode of its distribution." Nor is this brought out in any of the small number of figures which Prof. Moebius gives of the *internal casts* obtained by decalcification. Now to any one who will picture to himself how imperfect would be any conception he could form of the ramification of a *tree*, by taking a number of sections of its stem and system of branches through different planes, it must be obvious that "internal casts," in relief, when well preserved, will give a representation of the canal-system, which must be much truer than any conception can be that is based on a comparison of sections only; and that, in fact, it is only when the sections are interpreted by such solid models, that the real forms and relations of these "canal-systems" can be made out.

Having been kindly furnished by Prof. Dawson some months ago, with a large amount of new material, consisting of numerous specimens of *Eozöon*, obtained from different localities and in different states of mineralisation, I am now able to assert with confidence that the peculiar distribution described and figured by me from the actual specimens (one of which has been in Prof. Moebius's own possession) five years ago,[1] is the *regular and characteristic "canal-system" of Eozöon*. For my cabinet now contains *hundreds* of examples of it, both in transparent sections and in the solid models obtained by decalcification; and these last, in partially "dolomitised" specimens of *Eozöon*, show the following singular peculiarities, which do not seem to have fallen under Prof. Moebius's observation. When a band of dolomite runs through the calcite layers, (1) the "canal systems" in its neighbourhood are very commonly filled with *dolomite*, instead of with serpentine; (2) in one and the same canal-system, some of the branches are often filled with dolomite, and others with serpentine; while (3) individual branches are often partly filled with one mineral and partly with the other.

How these facts can be explained, except by the *pre-existence of a system of canals in the calcareous layers* into which these minerals have penetrated, I must confess myself unable to conceive; and that they thus afford demonstrative evidence of a structure which cannot be otherwise than *organic* is not merely my own opinion, but that of such accomplished petrologists as Prof. Geikie, who has been for some years engaged in the microscopic study of the metamorphic rocks of Scotland, and Prof. Bonney, who has been similarly studying the Cornish serpentines.

Whether, when taken in connection with the general structure of the organism, these "canal-systems" indicate its *Foraminiferal* affinities is, of course, an altogether different matter. To Prof. Moebius the difference seems greater than the resemblance; but it is noteworthy that his comparisons are limited to types examined by himself, and do not extend to *Calcarina*, in whose "canal-system" Dr. Dawson and I recognise the nearest approach to that of *Eozoön*. To myself, as to the late Prof. Max Schultze,[2] the resemblance seems greater than the difference. And as the several "canal-systems" of *Nummulina*, *Polystomella*, *Calcarina*, *Tinoporus*, and *Cycloclypeus* (all originally worked out by myself) *differ from each other* in plan, I cannot regard it as a valid argument *against* the foraminiferal affinities of *Eozöon* that its canal-system has a plan of its own. Surely Prof. Moebius would not deny the foraminiferal characters to any new *recent type* that the *Challenger* or any other collection may yield, if it should show a plan of canal-system different from any yet known, and approximating to that of *Eozöon*.

That in its *general plan of growth* (to which the distribution of the canal-system is intimately related) *Eozöon* differs from all recent *Foraminifera* at present known cannot be regarded as a proof of its *non*-foraminiferal character by any who have fully studied the very wide range of forms which that group comprehends, including the numerous indefinite "arenaceous" types, whose import is only now beginning to be understood by those who have the best opportunities of studying them.

I would suggest this further consideration: If we are to relegate to the mineral kingdom every supposed fossil that does not conform to any known existing type, we must expunge not only *Eozöon*, but *Stromatopora*—to say nothing of many other fossils whose place no one has yet been able to assign with certainty. Now, is Prof. Moebius prepared to say that *Stromatopora* is a "pseudomorph," because one zoologist thinks it a coral, another a sponge, and another a foraminifer? On his method of "differences" it is clearly neither one of these; and must, as he says of *Eozöon*, be either shut out of the animal kingdom altogether, or be made to constitute a sub-kingdom in itself. To myself it appears more philosophical to suppose that such "archaic" types combined in themselves characters which were afterwards specialised as those of distinct groups. And following this clue, I find in the chambered structure of *Eozöon*, and in its general relations to the canal-system traversing its calcareous layers, points of essential conformity to the group of *Foraminifera*, which seem to me far to outweigh the differences of detail by which Prof. Moebius has been led to the opposite conclusion.

I limit myself to this special point, because an excellent general criticism of Prof. Moebius's memoir, from the pen of Dr. Dawson, has already appeared in the *American Journal of Science*; and I hope that as you have given so much prominence to the views put forth by Prof. Moebius, you will do Dr. Dawson

[1] I think it rather hard that an *early diagram* of mine should be cited, and made the subject of adverse criticism, while those more recent *representations of actual structures* are ignored.

[2] I have been informed on good authority that Prof. Max Schultze left behind him for publication an elaborate and beautifully illustrated memoir on *Eozöon*, arguing for its foraminiferal character on account of the *resemblance* of its "canal-system" to that of existing types.

and myself the justice of placing before your readers his statement of objections to them, in which I fully concur.

Hereafter I think I shall be able to show that the "cumulative argument in favour of the organic character of *Eozöon* is as strong as that of the human origin of the "flint implements." Any one of the fractures that has given to these their characteristic forms, *might* have been accidental; and yet it is impossible to conceive that any number of such flints can have been so shaped "by accident." WILLIAM B. CARPENTER

London, July 28

The following is the communication from Principal Dawson referred to by Dr. Carpenter:—

Eozöon canadense has, since the first announcement of its discovery by Logan in 1859, attracted much attention, and has been very thoroughly investigated and discussed, and at present its organic character is generally admitted. Still its claims are ever and anon disputed, and as fast as one opponent is disposed of another appears. This is in great part due to the fact that so few scientific men are in a position fully to appreciate the evidence respecting it. Geologists and mineralogists look upon it with suspicion, partly on account of the great age and crystalline structure of the rocks in which it occurs, partly because it is associated with the protean and disputed mineral serpentine, which some regard as eruptive, some as metamorphic, some as pseudomorphic, while few have had enough experience to enable them to understand the difference between those serpentines which occur in limestones, and in such relations as to prove their contemporaneous deposition, and those which may have resulted from the hydration of olivine or similar changes. Only a few also have learned that *Eozöon* is only sometimes associated with serpentine, but that it occurs also mineralised with loganite, pyroxene, dolomite, or even earthy limestone, though the serpentinous specimens have attracted the most attention, owing to their beauty and abundance in certain localities. The biologists on the other hand, even those who are somewhat familiar with foraminiferal organisms, are little acquainted with the appearance of these when mineralised with silicates, traversed with minute mineral veins, faulted, crushed, and partly defaced, as is the case with most specimens of *Eozöon*. Nor are they willing to admit the possibility that these ancient organisms may have presented a much more generalised and less definite structure than their modern successors. Worse, perhaps, than all these, is the circumstance that dealers and injudicious amateurs have intervened, and have circulated specimens of *Eozöon*, in which the structure is too imperfectly preserved to admit of its recognition, or even mere fragments of serpentinous limestone, without any structure whatever. I have seen in the collections of dealers, and even in public museums, specimens labelled "*Eozöon canadense*" which have as little claim to that designation as a chip of limestone has to be called a coral or a crinoid.

The memoir of Prof. Moebius affords illustrations of some of these difficulties in the study of *Eozöon*. Prof. Moebius is a zoologist, a good microscopist, fairly acquainted with modern foraminifera, and a conscientious observer; but he has had no means of knowing the geological relations and mode of occurrence of *Eozöon*, and he has had access merely to a limited number of specimens mineralised with serpentine. These he has elaborately studied, and has made careful drawings of portions of their structures, and has described these with some degree of accuracy; and his memoir has been profusely illustrated with figures on a large scale. This, and the fact of the memoir appearing where it does, convey the impression of an exhaustive study of the subject, and since the conclusion is adverse to the organic character of *Eozöon*, this paper may be expected, in the opinion of many not fully acquainted with the evidence, to be regarded as a final decision against its animal nature. Yet, however commendable the researches of Moebius may be, when viewed as the studies of a naturalist desirous of satisfying himself on the evidence of the material he may have at command, they furnish only another illustration of partial and imperfect investigation, quite unreliable as a verdict on the questions in hand. The following considerations will serve to indicate the weak points of the memoir:—

1. A number of errors and omissions arise from want of study of the fossil *in situ*, and from want of acquaintance with its various states of preservation. Trivial errors of this kind are his referring to my photograph in Plate III. of the "Dawn of Life," as if it were natural size, and his stating that the larger specimens have fifty laminæ, whereas they often have more than a hundred. More important is his failing to appreciate aright the occurrence of *Eozöon* in certain layers of regularly bedded limestones, the rounded or club-shaped forms of the more perfect specimens, the manner in which the layers become confluent at the edges of the forms, as described by Sir W. E. Logan and myself, or the amount of crushing and fracture which most of the specimens exhibit. Thus he fails to convey any adequate idea of the Stromatoporoid forms and mode of occurrence of the organism, or indeed of its general character and probable mode of growth. Further, he treats it from the first as a mere laminated aggregate of calcite and serpentine, without reference to its occurrence in any other state, and also without reference to the fragmental limestones in part made up of its remains. He objects strongly to the want of definiteness of form and distribution in the chambers and connecting passages, without making allowance for defects of preservation, or mentioning the similar want of defined form in some *Stromatoporæ*. He admits, however, that the modern *Carpenteria* and its allies are in some respects equally indefinite. He further objects to the impossibility of detecting regular primary chambers like those in modern foraminifera, but seems not to be aware that, as I have recently shown, some *Stromatoporæ* originate in a vesicular, irregular mass of cells, and that in *Loftusia*, both the eocene *L. Persica* and the carboniferous *L. Columbiana*, the primary chamber is represented by a merely cancellated nucleus.[1]

2. With reference to the finely tubulated proper wall of *Eozöon*, he has fallen into an error scarcely excusable in an observer of his experience, except on the plea of insufficient access to specimens. He confounds the proper wall with the chrysotile veins traversing many of the specimens, and obviously more recent than the bodies whose fissures they fill. That he does so is apparent from his stating that the proper wall structure sometimes crosses the bands of serpentine and calcite, and also that it presents a series of parallel four-sided prisms, whereas, when at all perfectly preserved, it shows a series of cylindrical threads penetrating a calcite wall. That some of his specimens have contained the proper wall fairly preserved is obvious from his own figures, in which it is possible to recognise both this structure and chrysotile veins, though confounded by him under the same designation. He objects, somewhat naïvely, that many of the chambers fail to exhibit this nummuline wall, and that it sometimes presents a ragged appearance or is altogether opaque. In point of fact it can appear distinctly, either in decalcified specimens or in slices, only when the minute tubes are filled with some substance optically distinguishable from calcite, or not acted on by dilute acid. When the proper wall is merely calcareous (and I have specimens showing that it is often in this state, and without any serpentine in its pores), its structure is ordinarily invisible, and it is the same when the calcareous skeleton has from any cause lost its transparency or has been replaced by some other mineral substance. Even in thickish slices, the tubes, though filled with serpentine, may be so piled on one another as to be indistinct. All this may be seen in tertiary *Nummulites*. When wholly calcareous their tubulation is often quite invisible, and when imperfectly injected with glauconite or other silicates, they often present a very irregular appearance. If Prof. Moebius will study the Nummulites injected with glauconite from Kempten,[2] Bavaria, in addition to the casts of *Polystomella* from the Ægean, to which he refers, he will be better able to appreciate these points. It may be worth repeating here that, in examining the original specimens of *Eozöon*, I did not recognise the proper wall. I did not doubt that it must have existed in some form, since I could easily detect the canals in the supplemental skeleton; but I did not wonder at its non-appearance, knowing the chances against its preservation in a recognisable form. Its discovery was due to the subsequent investigations of Dr. Carpenter.[3]

3. To the canal system, Prof. Moebius does more justice and admits its great resemblance to the forms of this structure, in modern *Foraminifera*. This indeed appears from his own figures, which well show how wonderfully this structure has

[1] See *Journal* of London Geol. Soc., January, 1878.

[2] I am indebted to Mr. Otto Hahn for specimens of these most interesting fossils.

[3] It may deserve mention here that the carboniferous *Fusulina* very rarely shows it tubulated wall, and that Dr. Carpenter had maintained its Nummuline affinities before he obtained specimens showing this particular structure. Structures so delicate as these are indeed only preserved exceptionally in fossil specimens.

been preserved, and how nearly it resembles the similar parts of modern *Foraminifera*. He thinks, however, that these round and regularly branching forms are rather exceptional, which is a mistake; though it is true that the sections of the larger canals are often somewhat flattened, and that they become flat where they branch. They are also sometimes altered by the vicinity of veinlets or fractures, or by minute mineral segregations in the surrounding calcite, accidents to which all similar structures in fossils are liable. Another objection, not original with him, is derived from their unequal dimensions. It is true that they are very unequal in size, but there is some definiteness about this. They are larger in the thicker and earlier formed layers, smaller or even wanting in the thinner and more superficial. In some slices the thicker trunks only are preserved, the slender branches having been filled with dolomite or calcite. It is difficult, also, to obtain, in any slice or any surface, the whole of a group of canals,[1] Further, as I have shown, the thick canals sometimes give off groups of very minute tubes from their sides, so that the coarser and finer canals appear intermixed. These appearances are by no means at variance with what we know in other organic structures. Another objection is taken to the direction of the canals, as not being transverse to the laminæ but oblique. This, however, may be dismissed, since Moebius has of course to admit that it is not unusual in modern *Foraminifera*. It may be added that some of the appearances which puzzled Moebius, and which are represented in his figures, evidently arise from fractures displacing parts of groups of canals, and from the apparently sudden truncation of these at points where the serpentine filling gives place to calcite. It would also have been well if he had studied the canal systems of those *Stromatoporæ* which have a secondary or supplemental skeleton, as *Cœnostroma* and *Caunopora*.

4. A fatal defect in the mode of treatment pursued by Moebius is that he regards each of the structures separately, and does not sufficiently consider their cumulative force when taken together. In this aspect, the ease of *Eozöon* may be presented thus: (1) It occurs in certain layers of widely distributed limestones, evidently of aqueous origin, and on other grounds presumably organic. (2) Its general form, lamination, and chambers, resemble those of the silurian *Stromatopora* and its allies, and of such modern sessile foraminifera as *Carpenteria* and *Polytrema*. (3) It shows under the microscope a tubulated proper wall similar to that of the Nummulites, though of even finer texture. (4) It shows also in the thicker layers a secondary or supplemental skeleton with canals. (5) These forms appear more or less perfectly in specimens mineralised with very different substances. (6) The structures of *Eozöon* are of such generalised character as might be expected in a very early Protozoan. (7) It has been found in various parts of the world under very similar forms, and in beds approximately of the same geological horizon. (8) It may be added, though perhaps not as an argument, that the discovery of *Eozöon* affords a rational mode of explaining the immense development of limestones in the Laurentian age; and on the other hand that the various attempts which have been made to account for the structures of *Eozöon* on other hypotheses than that of organic origin have not been satisfactory to chemists or mineralogists, as Dr. Hunt has very well shown.

Prof. Moebius, in summing up the evidence, hints that Dr. Carpenter and myself have leaned to a subjective treatment of *Eozöon*, representing its structure in a somewhat idealised manner. In answer to this it is necessary only to say that we have given photographs, nature-prints, and camera-tracings of specimens actually in our possession. We have not thought it desirable to figure the most imperfect or badly preserved specimens, though we have taken pains to explain the nature and causes of such defects. Of course, when attempts at restoration have been made, these must be taken as to some extent conjectural; but so far as these have been attempted they have consisted merely in the effort to eliminate the accidental conditions of fossilised bodies, and to present the organism in its original perfection. Such restorations are not to be taken as evidence, but only as illustrations to enable the facts to be more easily understood. It is to be observed, however, that in the study of such fossils as *Eozöon*, the observer must expect that only a small proportion of his specimens will show the structures with any approach to perfection, and that comparison of many specimens prepared in different ways may be necessary in order to understand any particular feature. A single figure or a short description may thus represent the results of days spent in the field in collecting, of careful examination and selection of the specimens, of the cutting of many slices in different directions, and of much study of these with different powers and modes of illumination. My own collection contains hundreds of preparations of *Eozöon*, each of which represents perhaps hours of labour and study, and each of which throws some light more or less important on some feature of structure. The results of labour of this kind are unfortunately very liable to be regarded as subjective rather than objective by those who arrive at conclusions in easier ways.

Taken with the above cautions and explanations, the memoir of Prof. Moebius may be regarded as an interesting and useful illustration of the structures of *Eozöon*, though from a point of view somewhat too limited to be wholly satisfactory.

[1] I have succeeded best in this by etching the surface of broken specimens.

THE COLOURS OF DOUBLE STARS

IN a recent number of the *Bulletin de l'Académie royale de Belgique*, M. Niesten, of the Brussels Observatory, has published some interesting details relating to the colours of double stars, to which subject he has given special attention for a considerable time past. When comparing the periodicity of solar spots with the longitudes of planets in the ecliptic, Messrs. De la Rue, Balfour Stewart, and Loewy had found that a distinct connection exists between solar activity and the relative positions of the different members of our planetary system. A long time ago the attention of astronomers had already been drawn to the fact that Wolf's sun-spot period of eleven years coincides with the period of Jupiter's revolution round the sun. Later on Prof. Balfour Stewart pointed out that the coincidence of the perihelia of Jupiter and Saturn, which occurs about every fifty-nine years, corresponds to another one of Wolf's spot-periods.

If, therefore, the relative positions of the planets with regard to the sun have some influence upon the activity of that luminary, the question is justifiable whether on the other hand the influence of the sun upon the planets might not be apparent through some slight changes in their colour. There is no doubt that the colours of the planets actually do change; their brightness increases and decreases according to their position near the perihelion or aphelion. In the case of Jupiter changes of colour have been repeatedly observed, and they seem to coincide with the sun-spot periods. At the last opposition of Mars, when the planet was near its perihelion, it seemed to be less ruddy than usual; Uranus, which was generally described as shining with pale bluish light, is now, when it is approaching its perihelion, remarkable by its bright white lustre.

These relations between the sun and the planets induced M. Niesten to search for similar relations among the double stars, and specially to try to answer the question whether the changes of colour which have taken place in several double-star systems are in any way connected with the relative position of the components of a double star. For this purpose he collected the observations of astronomers who have given special attention to the colours of stars, and catalogued the colours of the stars visible in our horizon. It was found that many double-stars have not changed in colour since they were first observed, while others in a period of more or less considerable duration have shown a series of changes of colour, which seem to follow a definite law. The changes of colour were particularly remarkable in those double stars which possess great velocity of revolution. M. Niesten gives a table in which the different colours of twenty double stars of known period and periastrium, *i.e.*, the colours of the principal star and of the companion, as observed at different periods, are compiled. From M. Niesten's discussion of the facts revealed by this table, we will give that relating to the first two double-star systems by way of example.

In 70 *p* Ophiuchi, the period of revolution of which is 94·37 years, and for which the periastrium occurred in 1807, the colour of the principal star at Herschel's time (an epoch closely preceding the periastrium) was white; the star then changed in colour, passing from white, through yellow and pale topaz-coloured to golden yellow, reaching this tint about 1854. From this period it showed a tendency to return to white, passing through yellow and pale yellow. In 1877 Mr. Pritchard designated it as pale yellow, and afterwards as white. The companion during its revolution showed similar fluctuations of colour to those of the principal star. In the vicinity of the periastrium Herschel put it down as reddish (we must remember here that Herschel's

speculum gave a slight reddish tint to all objects); now the companion is bluish white, and between these two epochs it showed more saturated colours.

The short period of ζ Herculis (34·32 years) allows us to consider the changes of colours during two revolutions. Herschel measured this system about the epoch when the companion was very near to the primary; the latter was white, the former ash-coloured. At the periastrium of 1860 Mr. Knott saw them pale yellow and greenish respectively; at other epochs the colours of the two components are all the more marked the further they are away from the periastrium, the companion always showing warmer tints than the principal star. About the epoch of the apparent periastrium M. Dembowsky designated them as yellow and olive colonred. Similar phenomena are shown by the other donble stars given in the table, all of which are systems with closed, *i.e.*, elliptical orbits. In the double star 61 Cygni, where no closed orbit has been observed, but where the small companion moves in a straight line relatively to the larger one, the same yellow tint has been observed from 1828 to 1873.

In the cases of optical double-star systems, *i.e.*, those which only accidentally happen to be in the same line of sight, and which show a rectilinear motion, the principal star is generally yellow and the companion blue. In Mr. Brothers' catalogue, which comprises 105 double-star systems, with closed orbits, there are only thirty-two where the companion is blue, while all the others show the same colour as the principal star. And even these thirty-two systems may possibly be optical ones, in which the companion is almost exclusively blue. The absence of blue in the companions of double stars of short period is most remarkable.

The blue colour of the companions in the optical systems is not an effect of contrast to the yellow colour of the primaries, for the former are blue even if the latter are shut out of the field of vision. It seems possible that, similar to the effect in our atmosphere, where distant objects assume a bluish tint, celestial bodies which send us their rays of light from the most distant regions, may appear blue on account of the thickness of the medium through which the light passes.

M. Niesten has compiled a table of double stars with blue companions, and has arranged them according to their position in declination and right ascension. From this it appears that these double stars are principally situated in a zone extending from decl. 10° S. to 40° N., and further that there are two maxima of occurrence, one in R.A., 4h.-6h. and the other in R.A. 18h.-20h.; the first maximum is near the equator, the other between Decl. 30° and 40° N.; the former is therefore in the constellation of Orion, the latter in Cygnus and Lyra. According to Sestini, the single blue stars occur in the same parts of the heavens.

The conclusions we may draw from M. Niesten's researches are as follows:—

1. In systems with well-established orbits, and particularly in those of short period, the two components generally have the same yellow or white colours.

2. In systems of which we possess sufficiently numerous records of the colours of the components to enable us to perceive a relation between the tints and the relative positions of primary and companion, the former is white or pale yellow when the latter is in its periastrinm, while in other positions the primary is yellow, golden yellow, or orange.

3. In these systems the companion follows the colour-fluctuations of the principal star, and frequently surpasses the latter in intensity of tint the further it moves away from the periastrium, at which point in most cases its light is white, like that of the primary.

4. An equality of tints of primary and companion is found in systems with rectilinear motion, as well as in those with closed orbits and long periods.

5. In optical groups the companion is generally blue.

These remarks are, of course, founded upon observations made by different observers, and the records of colour may thus suffer from personal influences; but in many cases one and the same observer recorded the colours of the components of a system as yellow during a series of years, and then he saw them grow paler and turn white. In other instances all astronomers agree that a certain companion is blue.

When more careful attention has been given to the question of colours, both in measuring double stars as well as in investigations of the physical condition of planets, then it will be possible, perhaps, to draw a great many more conclusions, and such to which greater probability attaches, than was in the power of M. Niesten, with the comparatively small number of observations at his command.

At present it is supposed that the fluctuations of colour in stars are caused by changes in the composition of their incandescent gaseous envelopes; these changes must in turn be only effects of another cause producing them; M. Niesten does not think it impossible that in the case of double stars this cause might lie in the relative position of the components.

SCIENTIFIC SERIALS

American Chemical Journal, vol. i., Nos. 2 and 3, present a good array of contributions from different American universities, making in all, with reviews and reports, about 215 pages. Under inorganic chemistry is to be found a description of very slightly modified methods of nitrogen and phosphorus estimation adapted to agricultural products, by Johnson and Jenkins; and a series of analyses of gummite and other uranium minerals from North Carolina, by E. Genth, &c. Among the contributions to organic chemistry is a long paper by Remsden and Iles on the oxidation of substitution products of aromatic hydrocarbons, continued from No. 1. In the first portion the authors describe solid orthokresol from their oxytoluic acid, and they further conclude from their experiments that the presence of a sulphamine group acts protectively towards a methyl group in a substituted aromatic compound submitted to oxidation. A full abstract of this and another interesting paper by Remsden and Morse on oxidation of bromparaethyltoluene, and researches on substituted benzyl compounds, by Jackson, cannot be given in our space. Thorpe on heptane has appeared elsewhere. The remaining communications are of minor interest.

Bulletin de la Académie Royale des Sciences (*de Belgique*), No. 5.—The yellow substance obtained when tetrathionic acid is poured into a solution of mercurous nitrate in water has been proved by M. Spring to be a *trithiobasic sulphate of mercury*. This substance showed some unexpected chemical properties, which M. Spring describes, and he has succeeded in forming some other new bodies similar to it, so as to complete the list of basic sulphates of mercury sufficiently for an attempt at classification of these substances.—The recent terrible catastrophe at the Agrappe coal-pit is the occasion of two communications by M. Cornet and M. Melsens, the former remarking especially on the influence of depth on the instantaneous irruption of fire-damp, and the proportion of that gas met with. (The fire-damp of the Agrappe pit, which ignited at the mouth of the pit, came from 610 metres depth, where a new gallery was being made.)—M. Renait's paper on the distinctive characters of dolomite and calcite in rocks of the carboniferous limestone of Belgium is elsewhere noticed.—There are also here two notes on Belgian minerals.

THE *Rivista Scientifico-Industriale*, Nos. 11-13, contain the following papers of importance:—Researches on the electric conducting power of carbons, by Prof. Rinaldo Ferrini.—On some new applications of the potential energy of liquid surfaces, by G. Van der Mensbrugghe, discussed by Prof. C. Marangoni.—On a telephonic microphone, by Prof. G. Cantoni.—On the endosmose of liquids and on an apparatus for filling endosmometers, by Prof. C. Marangoni.—On the mutual dependence of simple bodies, by P. Provenzali.—On some prehistoric discoveries made at Ostiano, by Dr. Ciro Chistoni.—On a new saccharometer or polarimeter, by M. Laurent.—On the kinzigite of Calabria, by Domenico Lovisato.—On the determining causes of the sexuality of *Cannabis sativa*, by Prof. P. A. Saccardo.—On the constitution of fog and clouds, by Prof. Fernando Palagi.—On a new burner for monochromatic light.—On the phenomena which accompany the electrolysis of metallic compounds, by Prof. Giuseppe Basso.—Crystallographical, optical, and chemical researches on certain minerals, by Prof. Giuseppe Grattarola.—On a new method to determine the melting-point of organic substances, by Prof. Giorgio Roster.

THE *Revue Internationale des Sciences* (June and July).—From these parts we note the following papers:—Analysis of Prof. Ernst Haeckel's treatise, "Monogenetic and Polygenetic Origin of the three Organic Kingdoms and of the Organs," by Jules Soury.—Description of the scientific balloon ascent of October 31, 1878, and remarks on the exploration of great aërial heights, by Louis Tridon.—On the Diatomaceæ of the mouth of

the Seine, by M. Manoury.—On the secreting and trophic nerves of glands, by R. Heidenhain.—On the colouring-matter of urine, by M. Masson.—On the beginnings of art, by Dr. Johannes Ranke.—On the circulation of gases and some phenomena of gaseous thermo-diffusion in plants, by J. L. de Lanessan.

Reale Istituto Lombardo di Scienze e Lettere, Rendiconti, vol. xii. fasc. xiii.—We note here the following:—Anatomical and statistical note on cirrhosis of the liver, by Prof. Sangalli.—On albinism in batrachians, by Prof. Pavesi.—On polar systems (continued), by Prof. Jung.—On monodromic functions having a characteristic equation, by S. Pincherle.—Rapid preparation of hydroxylamine, by Dr. Bertoni.

SOCIETIES AND ACADEMIES

Paris

Academy of Sciences, July 21.—M. Daubrée in the chair.—The following papers were read:—Theory of the simple pendulum with conical oscillations, regard being had to the rotation of the earth, by M. Villarceau. He concludes that other causes than gravity and the earth's rotation intervene.—Various thermo-chemical data, by M. Berthelot. This relates to formation of diamylene, and heat of fusion and specific heat of glycerine.—Remarks on the last communication of M. Bouquet de la Grye, by M. Ledieu. He doubts the possibility of determining, even approximately, the influence of the sun and the moon on atmospheric pressure.—The last three epidemics of plague of the Caucasus, studied with regard to epidemiology and prophylaxy, by M. Tholozan. These epidemics appeared in 1804-18, 1828-30, and 1840-43. He remarks on the inefficacy of means expected to be effectual for staying the progress of the disease.—M. Schwann was elected correspondent in Medicine and Surgery, in place of M. Rokitanski.—Astronomical observations and measurement of an arc of parallel in Algeria, by M. Perrier. The arc embraces 10°. The triangulation is destined to serve for basis and control of the vast system covering Europe.—Anæsthesia by means of protoxide of nitrogen mixed with oxygen, and employed under pressure, by M. Bert. One operation, by M. Labbé, is described, and sixteen, by M. Pean, referred to. The superiority of the method is chiefly shown in the instantaneousness of the sleep and awaking. There is hardly any nausea. The excess of pressure varied between 0·15 m. and 0·22 m.—Researches on the causes of reinvasion of phylloxerised vineyards, by M. Boiteau.—M. Colladon announced the death of M. Favre, contractor of the Saint Gothard tunnel.—Discovery of a small planet by Mr. Peters at Clinton (N.Y.), on July 17, 1879.—On a generalisation of periodic functions and on certain linear differential equations, by M. Picard.—Hydrodynamic experiments with vibrating bodies, and imitation, in an inverse sense, of the forces of electricity and magnetism, by M. Bjerknes. He describes a modified form of his former apparatus.—On a phenomenon similar to that of Peltier, by M. Bouty. This relates to the experiment with metallised thermometers as electrodes, referred to elsewhere.—On the capacity of voltaic polarisation, by M. Blondlot. The following law is deduced from observations:—For a given electrode and a given electrolyte the initial capacity does not depend on the direction of polarisation.—Action of magnetism in motion on static electricity, by M. Lippmann. This action results rigorously from the existence of the inverse phenomenon, which Mr. Rowland's experiments have demonstrated; and this reversibility is a consequence of the impossibility of perpetual motion. Further, static electricity has a proper mechanical inertia, simply added to that of the electrified body.—On the laws of variations of atmospheric electricity deduced from regular observations made at the Moncalieri Observatory, by M. Denza. *Inter alia*, there are two principal daily maxima, a few hours after sunrise and sunset. The monthly electric tension reaches a maximum in February, a minimum in September. In twelve years negative electricity appeared with rain and snow, at least in 50 per cent. of the cases. The electric tension generally diminishes with the altitude.—Researches on explosive substances, by MM. Nobel and Abel.—Experimental researches on decomposition of gun-cotton in a closed vessel, by MM. Sarrau and Vieille. The pressure, heat, and volume and composition of the gases, are indicated. The latter are simple and few.—On the employment of sulphuretted hydrogen by the dry method in analyses, by M. Carnot. This mode of sulphuration has advantages, in many cases, over that of fusion with sulphur.—On the transformation of hydrocellulose into pulverulent pyroxyles, by M. Girard.—Action of fluoride of boron on acetone, by M. Landolph.—On the determination of urea, by M. Mehn.—On iron reduced by hydrogen, by M. Moissan.—Electric excitation of the point of the heart, by MM. Dastre and Morat. A series of closely successive currents may have on the heart the effect of a continuous current.—Note on the physiological action of bromhydrate of conine, by M. Prevost.—On the biliary secretion, by M. Picard. There are two differences between this and the renal secretion:—(1) An arterial system furnishes urine, a venous system bile; (2) In the biliary secretion certain substances formed in the liver are carried away by the outward movement of the liquid.—Action of the principal poisons on crustacea, by M. Yung. Strychnine and nicotine act with extreme violence; curare is less active than with vertebrates; sulphate of atropine never caused death; digitaline renders the heart's movements slower, &c.

Vienna

Imperial Academy of Sciences, May 8.—The following among other papers were read:—Old and new methods of solving differential equations by simple determinate integrals, by Prof. Winckler.—Researches on liverworts (Riccieæ), by Prof. Leitgeb.—Determination of path of two fireballs observed on January 12 in Bohemia and neighbouring regions, by Prof. Niessl.—On the employment of quarter-tones in music on the doubly chromatic piano, by Herr Gruss.—New conchylia from Mediterranean strata, by Dr. Hilber.—Diluvial land-snails from Greece, by the same.—On the *rôle* of the *Ligamentumiridis pectinatum*, by Dr. Biggs.—On compounds from animal tar, I. Picolin, by Prof. Barth.—On the internal friction in a mixture of carbonic acid and hydrogen, by Dr. Puluj.

May 15.—On the electro-magnetic rotation of the plane of polarisation of light in air, by Prof. Lippich.—On arsenate of zinc and cadmium, by Herr Demel.—On two peculiar surfaces of the sixth order, and on a certain group of curves of the third and fourth order, by Herr Cantor.—On tertiary fossils brought by Dr. Tietze from Persia, by Herr Fuchs.

May 23.—On the formation of cinchomeronic acid from chinine, and its identity with a pyridindicarbonic acid, by Dr. Weidel and Herr Schmidt.—Action of oxalic acid on carbazol, by Dr. Sinda.—On the decomposition of sulphydantoin by baryta hydrate, and on a peculiar iron-reaction of thioglycolic acid, by Herr Andreasch.—On bromoxyl derivatives of benzol, by Dr. Benedikt.—On the fossil fauna of the Vypustek cave in Moravia, by Prof. Liebe.

SCIENCE TEACHING IN SCHOOLS

SIR JOHN LUBBOCK, one of the two or three members of Parliament who know what science means, has again brought forward his motion for the introduction of science teaching into schools. As on former occasions, the motion was lost, though those who opposed it, and especially those connected with the Education Department, were at a loss to give any clear reason for not agreeing to it. One of the chief reasons apparently why the Department is afraid to hold out inducements for the teaching of scientific subjects, is that there is scarcely an inspector qualified to examine on the subject, a humiliating revelation of the lamentable state of education at our universities. But Sir John Lubbock also pointed out another apparently trivial but really powerful reason for our half-educated rulers shrinking from assenting to the introduction of science teaching into schools; the very name "science" acts as a bugbear. It is indeed a pity we have no such word as *Naturkunde* to indicate the sort of thing—"Natural Knowledge"—that Sir John Lubbock and the intelligent minority who are with him, wish to be taught to the boys and girls of our elementary schools. The fact is that what is wanted is a knowledge of things instead of mere words; it is really a question of how to use the eyes and how to train the mind; the pages of nature as opposed to the pages of a book; in brief, education *versus* mere instruction. How deeply working men feel the want of natural knowledge when they grow up is shown by the increasing number of technical schools that are springing up, evening classes for the teaching of science, popular scientific lectures, local scientific societies, and other similar efforts to make up for a deficient education in youth. It seems simply incomprehensible how any member of Parliament having at heart the real welfare of the people, physical, intellectual, and moral, should not heartily support Sir John Lubbock's attempt to give something like reality to our elementary education. Even the opponents of the motion seem to approve of "object-lessons," ignorant that science teaching, in Sir John Lubbock's acceptation, is just the same thing "writ large,"—simply object-lessons taught by competent teachers in a systematic and accurate manner. As to the outcry against increasing the burdens of teachers and pupils, those who raised it must have known that it was quite irrelevant. The advocates of science teaching do not wish to make it an additional, but only an alternative subject, to be taken at the option of the teachers, for grammar, geography, or other existing subject, for which payment is made. For indeed already is science put down as one of the subjects in elementary schools, but only as an extra subject for which no payment will be made, and for the teaching of which, therefore, no inducement is held out to the teachers. Then as to cost, Sir John Lubbock told the House—"Contrary to what was believed in some quarters, his proposal would really not involve any appreciable cost. The little books would come to no more than those on history or grammar; while the sun, moon, and stars, rain and dew, wind and light, air and water, heat and cold, stones and flowers, were before us all; and even if a few objects as illustrations were required, they could be obtained for a few shillings. He wished for nothing difficult or abstruse, nothing beyond the range of the children's minds and daily experience. In mechanics the simple forces might be explained to them—why carts were put on wheels, how levers and pulleys acted, the use of the screw and wedge; then the nature and relative distances of the principal heavenly bodies, the primary facts relating to air and water in agricultural districts, the character of the soil, the reason for the rotation of crops, the origin and principal qualities of such substances as chalk, coal, iron, copper, &c.; the succession of the seasons, the flow of rivers, the growth of plants; the fundamental rules of health, the necessity for ventilation and cleanliness, and last, not least, the need for industry, frugality, and economy. Explanations of these simple and every-day things would be most interesting and useful to the children. So far from cramming and confusing them, you would introduce light and order into their little minds, and give them an interest in their lessons which under the present system they rarely felt."

And, as Dr. Playfair put it, of what use was it to spend a long time in teaching children in mining districts grammar? Would it not be of greater importance to teach them about the dangers they would have to meet in their calling—about fire-damp and after-damp, for instance? In the same way, should not a child destined to become an agricultural labourer be taught something about the earth, the properties of manure, and other subjects connected with cultivation?

The fact is that some means should be taken to enlighten members of Parliament themselves as to what education, as contradistinguished from instruction, and natural knowledge. as contradistinguished from book knowledge, really is; and our readers might do worse at the certainly approaching election than arouse the minds of candidates to the urgent necessity of bringing the country, in the matter of science teaching, up to the level of those countries which, by the superior knowledge of their manufacturers and technical skill of their working men, are rapidly outstripping us on our own ground.

MAUDSLEY'S "PATHOLOGY OF MIND"

The Pathology of Mind. Third Edition. By Henry Maudsley, M.D. (London: Macmillan and Co., 1879.)

GREAT as has been the growth, in recent years, o the tree of knowledge, there is no branch in which it has undergone so much actual development, as well as mere expansion, as that of psychology. Though formerly nearly isolated, being as it were but imperfectly grafted on to the main stock, curious rather than beautiful, looking irregular, dry, and withered by the blight of theology and bad metaphysics, it now presents a compact system of branches and foliage, arranged with all the symmetry of organisation; the main stem springing from the branch of biology as this does, in its turn, from that of the physical sciences; moreover, the process is still continuing, for fresh buds may be seen in the newly-formed structures, some of which, *e.g.*, sociology, philology, æsthetics, and the science of religious beliefs are already beginning to unfold. The causes of this accelerated growth it is needless here to discuss; the principal seems to be the gradually extended application of natural law

which has taken place since the impulse it received long ago from Descartes; the more immediate causes being the greater development which biology has undergone, through both induction and deduction; and especially the advances made in the physiology of the nervous system, by which a clearer understanding has been obtained of the correspondence between consciousness and bodily state. It has come to be perceived that mind, instead of being considered as a substance superadded to the body, or even as the power of consciously knowing and acting, is better regarded as the power, more extensive than the field of reflection, which highly organised beings possess, of performing their most complex actions; this regulation of action being vested in the nervous system as its peculiar function. Thus, mind appears homogeneous with life—being power similar in kind, but differing in degree of speciality. Still, the eternal mystery of the connection of consciousness with the objects of consciousness remains almost the same; the gulf still gapes widely, and cannot be bridged, though perhaps its borders may be a little more clearly defined. Also, it may still be open to discussion whether an organism possesses these remarkable powers *necessarily—i.e.*, in virtue of its organisation.

The development of the science having proceeded so far, it might be considered not unreasonable to look for fruit on it already, in the shape of immediate practical application; and the belief that this search had been successful was the *raison d'être* of the first appearance of this work, as the author explains in his preface. Certainly some may consider the fruit as yet unripe, or at any rate the seed it contains unready for germination, but this would be matter of individual taste. For it is at least extremely probable that if mind be a function of the body, its health will depend on laws and conditions similar to those of the other vital functions; and that when disordered, similar methods of restoration will be serviceable in either case. But the common psychological doctrines were, till lately, quite inadequate to show in what mental disease consisted. Certain affinities with other diseases had long been recognised, *e.g.*, its dependence upon certain general bodily states, or being induced by definite causes; also the prominent features of pain, excitability, and weakness, separately or together, frequently characterised the derangement of other functions also. The author shows that the correspondence may be traced still further: that, like many other morbid conditions, insanity consists essentially in failure to attain to, or retrograde departure from, the normal stage of development. But in one respect especially the present edition claims and is entitled to some degree of novelty, or even originality; namely, in the recognition of the particular mental faculty which suffers lesion in insanity. Until pointed out by Comte, Spencer, and Lewes, how large a proportion of our total environment is constituted by society, sufficient attention had not been paid to the extensive position occupied by that faculty of the mind employed in regulating our actions in relation to the social medium. Just as the motion of a planet may be resolved into a purely individual movement of rotation, and an orbital movement which it performs as member of a system, so the activities of the human mind are partly concerned with the individual alone, partly dependent on the presence of other members of a system. The latter class absorb by far the greater part of the total activity, and really constitute the chief differentia between the mind of man and that of animals, comprising those altruistic impulses which are the highest development of our activity, as is well shown in Spencer's "Principles of Psychology"; but, like all recent highly developed faculties, they do not appear in the individual completely formed at first, but in a germinal state, requiring training and exercise to bring them to the condition of full perfection; and because of their difficult development are more prone to suffer degeneration. This notion forms the foundation of the theories of education and of insanity, the latter showing that when the higher functions fail to be developed, or fall into abeyance, their place is taken by less developed faculties, which preceded them in order of evolution; or, to return to the analogy employed above, the rotatory gains at the expense of the orbital movement. This view of faculties of higher and lower faculties, *i.e.*, of greater and less perfection, and their somewhat mutual opposition, is essentially the same as Spinoza's theory of ethics. It is the key-note of the present volume, the substance of which consists of the attempt to show its existence in nature.

If the execution of the book were as satisfactory as its conception, it would indeed deserve most unqualified praise; but it is impossible not to feel, on perusal of the work, that in many respects there is much shortcoming, leaving room for further improvement, the aim not being realised owing to the difficulty of the passage from the abstract to the concrete. For though the highest generalities appear correct, are clearly stated, and well enforced, yet there is much dearth of the less general laws—the "middle propositions" which Bacon describes as of such importance in understanding the details of a subject, and of such value in practice—the absence of which is acknowledged by the author, when he says that we do not at all know why the disease should present different aspects in different cases. Also, different parts of the book are of unequal value, the best decidedly being those devoted to pure psychology and mental pathology, in which varieties of character, morbid tendencies, and the various motives, impulses, feelings, &c., are discussed, the author finding abundant occasion to display his talents as a moralist and eloquence as a writer. Next in order of merit come the sections on the phenomena and treatment of insanity; the former of these, though clear, correct, and tolerably full, do not add much to what has been written by previous observers. Lastly comes the physical aspect of the subject, which seems decidedly weak; for though this is undoubtedly most obscure, yet there is much repetition of somewhat crude theories of the correspondence of physical with psychical states. The general pathology, too, is but feebly represented; it may, perhaps, be no worse than is usual in modern text-books, but its usefulness is greatly impaired by want of those invaluable "middle propositions" which are created by clinical genius and communicated by tradition.

The first chapters are new, and are devoted to the consideration of sleep, dreaming, somnambulism, hypnotism, &c., which, being states analogous to insanity, though more open to observation, might be looked to for illustration and explanation of the leading problems of the disease,

e.g., its nature and genesis. In this way, the author approaches the subject of delusion, which really, in its widest sense, may be said to constitute the essence of insanity; this problem is twofold: 1. What is the primary *mental* deviation? 2. On what bodily disturbance does this depend? The intellectual is shown to be convertible into and dependent upon emotional disturbance; and it is well demonstrated how much our state of feeling—whether temporary as mood, or permanent as character—influences not only the imagination, but even perception. A delusion may be regarded as a picture formed to suit a certain frame of mind. In showing how incorrect figures arise from morbid feelings, the author is less explicit; he adopts the sensationalist or association theory, but a clearer notion might probably be afforded by a more Platonic or idealistic theory of cognition, of which there even is some suggestion once or twice. Although the author adopts the emotional source of delusion as a rule, yet he makes—rightly or not—exception in certain examples of hallucination, *e.g.*, those arising in connection with epilepsy, some toxic conditions, and in childhood—which he assigns to primary derangement of the sensory centres. Owing to the defective state of general pathology, as before stated, the mode of dependence of feeling on corporeal condition is far from being satisfactory. Next follow long chapters on the causation and prevention of insanity, treated first on the psychical, then on the physical, aspect; in both, much stress is laid on heredity as a factor: the former contains the most interesting and original parts of the work. The rest of the volume is of more special and technical character, being given to a tolerably full and accurate description of the disease, which is regarded as fundamentally the same in all cases, though wearing some variety of aspects, thus affording matter for classification; that here adopted is the same as in previous editions: the description commences with a chapter on the insanity of early life, and concludes with one upon treatment, on which the author holds rather sceptical opinions concerning the efficacy of drugs, especially narcotics.

In conclusion we may remark that, although the author may be considered to have attained success in his chief aim—the setting forth of the pathology of mind—yet no more than a mere outline has been accomplished, and much of this appears to have been derived from borrowed rather than purely original ideas, the chief originality of the author lying in their present application; and it is to be regretted that it is so lacking in thoroughness, for this may suffice to prevent an otherwise highly-readable and well-designed book from acquiring extensive adoption as a text-book and permanence as a work of reference.

LUBBOCK'S SCIENTIFIC LECTURES

Scientific Lectures. By Sir John Lubbock, Bart., M.P., D.C.L., LL.D., &c. (London: Macmillan and Co., 1879.)

THE six lectures of which this volume consists treat of the relations of insects and plants, the habits of ants, and prehistoric archæology. They are well illustrated by numerous woodcuts, and are written in the clear and pleasing style which characterises all Sir John Lubbock's works.

The first lecture—On Flowers and Insects—gives an excellent account of some of the more interesting cases of the special adaptation of flowers for insect fertilisation, but contains nothing that will be new to the readers of NATURE. The next—On Plants and Insects—introduces us to a variety of interesting and less generally known relations between the insect and vegetable worlds, which serve to confirm in a striking manner the general axiom, that the minutest details in the structure of living things, are or have been of use to them. We learn now how much of what gives a special character to many plants—their hairy or woolly stems, their spines, their glutinosity, the hairy rings inside their flowers, their drooping habit or glossy surfaces—are all of use in various ways to keep off insects which would rob them of their honey or pollen without effecting fertilisation. Another relation here dwelt upon is that of the colouring of caterpillars in accordance with the plants they feed upon, and it is particularly instructive as showing how impossible it is to decide whether a creature is protected by its colour unless it is observed in its native haunts. Few objects are more beautiful, or more varied in colour and markings, than the caterpillars of our different species of hawk-moths. They are often adorned with the most exquisite violet, blue, or white markings on a green ground, and sometimes also with ocellated spots of brilliant colours, yet in most cases these are so arranged and balanced as to harmonise with the general tints of the foliage and flowers of the food plant and thus render the insect quite inconspicuous at a little distance. In addition to the excellent woodcuts of caterpillars which illustrate this part of the work there is a coloured frontispiece which appears to have been added as an afterthought, for not only is there no reference to it in the text, but not even the names of the insects are given on the plate itself.

The next two lectures—On the Habits of Ants—give an excellent summary of those interesting researches by which Sir John Lubbock has added so much to our knowledge of these insects. Especially curious are the illustrations of the stupidity of some ants. One species is such a confirmed slave-owner that it dies of hunger if not fed by its slaves—a fact recorded by Huber and confirmed by our modern observer. Even more striking as an example of want of intellect is the experiment recorded at p. 81, where some ants went round a distance of ten feet to get at honey rather than jump down about one-third of an inch; and although they tried to reach this small height, from a little heap of earth to the glass on which the honey was placed, and could even touch it with their antennæ, yet they had not sense enough to pile up the earth a little higher but gave it up in despair and went round by the paper bridge ten feet in length!

Numerous experiments show that some sense analogous to smell, rather than vision, guides ants to their food, and thus no actual power of communication from one ant to another is needed to account for the numbers that follow when one has found out a store. Some very ingenious experiments prove, however, that an actual communication does exist when larvæ are concerned, and that one ant is able to tell its fellows whether there are few or many larvæ to be attended to. The experiments as to the effects of coloured light on ants are interesting, showing

that they have a great dislike to violet light however obscure, and a preference for dark green and red; but we can hardly tell whether this effect depends on any visual perception, or on a general sense of discomfort in the one case and pleasure in the other analogous to the effects of heat and cold upon ourselves.

The last two lectures give a clear and condensed summary of the present state of our knowledge as to prehistoric man, and are well worthy of study by those who may be inclined to doubt the value of the conclusions arrived at by the new science of Prehistoric Archæology. There is here of course nothing but what is well known to all who have paid attention to the subject. It is, however, interesting to note how sharp and striking the contrast between the Palæolithic and Neolithic ages appears, when their characteristic features are briefly summed up side by side as we here find them. Whether we consider the tools, weapons, and other works of art, the character of the contemporary animals, the physical geography of the country, or the distribution of man himself, we cannot but be impressed with the profound chasm, which in Europe at least, separated the Palæolithic from the Neolithic man. And as, since the glacial epoch passed away we have no evidence of any physical changes calculated to produce such a chasm, it seems natural to suppose that it was the result of the cold period itself, and that, as many geologists now maintain, Palæolithic man lived before the glacial epoch and during interglacial mild periods, while Neolithic man made his first appearance only when the ice-age had finally passed away. On any other theory we have no adequate cause adduced for a discontinuity so vast in its proportions and extending over so wide an area.

A. R. W.

OUR BOOK SHELF

Dairy Farming; or, The Theory, Practice, and Methods of Dairying. By J. P. Sheldon, assisted by leading authorities in various countries. Part I. (London: Cassell, Petter, and Galpin, 1879.)

THE prospectus of this work promises us a thorough treatment of all parts of the important subject of dairy farming. The selection, breeding, and feeding of dairy cows; the production, treatment, and disposal of butter and cheese; the plants or crops used in feeding animals; dairy buildings, and soils adapted for dairy farms; such are some of the subjects embraced in the scheme of Mr. Sheldon's serial work, the publication of which, in monthly parts, has recently commenced. The first number, being chiefly occupied with general introductory remarks, hardly affords a fair sample of what the bulk of the book is likely to be. These prefatory pages do, however, contain a good deal of interesting matter—matter important to many persons besides dairy farmers. Some of the statistics of milk- and cheese-production here given are very striking. For instance, we are told (p. 9) that about 500,000 tons of ripe cheese could be made from the milk annually produced in the United Kingdom, when the quantity of milk required for rearing and fattening calves has been deducted. But, in point of fact, much milk is consumed as such in food, while from that which is submitted to further dairy operations a good deal of butter is made. The approximate estimates, therefore, for the amounts of milk and milk-products in question will stand somewhat as follows for the United Kingdom:—Milk annually consumed as such, 525,000,000 gallons; 126,000 tons ripe cheese from 350,000,000 gallons; 89,295 tons of butter from 550,000,000 gallons. When the cheese, butter, and condensed milk imported from abroad are added to the home production, some notion of the vastness of the amount of dairy products consumed by the population of the British Isles may be gained. Thus, 98,000 tons of cheese are annually brought into this country from the Continent, the United States, and Canada; while the yearly import of butter approaches 90,000 tons. The value of our imports of butter and cheese together is just 15,000,000*l.* sterling.

It seems somewhat ungracious to say one word in disparagement of any part of an undertaking which promises so well as does Mr. Sheldon's "Dairy Farming." But we feel bound to hint that more care should be taken in securing the accuracy of any physiological and chemical explanations that it may be thought expedient to introduce into the volume. The figures and statements on pp. vi. and vii. of the "Introduction" require revision. We give an instance. We are told (p. vi.) that 1 lb. of milk contains ·65 ounce of flesh-formers and 1·51 ounce of heat-givers. Now the latter figure has been reached by adding together the fat and sugar of the milk without the previous conversion of the former into its starch-equivalent. It is needless after this to say how idle are all the subsequent comparisons of milk with other foods, vegetable and animal.

Marcus Ward's Arithmetic. J. W. Marshall, M.A., Assistant-Master at Charterhouse School. (London: Ward and Co., 1879. 232 pp.)

THIS is a neatly got up arithmetic; it contains a great number of exercises, covering the usual ground occupied by such treatises, has a modicum of explanatory matter, and calls for no further comment. There are no answers at the end, but they can be got in a separate form.

A Collection of Problems on Plane Geometrical Drawing, including Problems on a few of the Higher Plane Curves, &c. By E. F. Mondy, A.R.S.M. 2 vols. Text and Plates. (Tokei. 127 and ix. pp.)

A COLLECTION of problems arranged for the use of the students in the Imperial College of Engineering, by the First Whitworth Scholar (1871), and Professor of Drawing in the College. The author's aim has been to arrange the earlier problems so as to render it of service to students to work these while reading Wilson's Geometry, the text-book used in the Mathematical Class. The treatment is mainly founded upon the recognised English text-books, but a novel feature, perhaps, is the extent of space devoted to the conic sections and the higher plane curves, "especially as regards the use of equations to these curves and to the various geometrical elements connected with them."

Thus constructions are given for the tangents and radii of curvature, and problems in areas are worked out.

The book is, under the circumstances, very fairly got up as regards the printers' work, and the matter is deserving of commendation for its arrangement.

Our own experience of Japanese students is that they take very kindly to this branch of mathematical instruction, and the productions of some we could name rank among the neatest we have seen. The plates are in a separate work from the text, a convenience in some respects for the student.

Essai sur les Principes fondamentaux de la Géométrie et de la Mécanique. Par M. de Tilly. (Paris: 1878. 190 pp.)

THIS valuable treatise forms the first *cahier* of the third volume of the *Mémoires de la Société des Sciences physiques et naturelles de Bordeaux*, 2e série. The first chapter—General Geometry—discusses the elementary notions and axioms of the subject in a way that will satisfy an anti-Euclidian, but we fear the nerves of Euclidian adherents would suffer a shock at the bare-

faced manner in which triangles and figures are moved about and turned about and placed upon one another.

The second chapter treats of the subject as handled in the Elementary Treatises, taking chiefly for the basis of remarks the fourth edition of the Geometry, by Messrs. Rouché and De Comberousse.

Chapters III. and IV. are occupied with Trigonometry, and Chapter V., closing the work, treats of Mechanics. The volume is too technical to allow of an extended criticism here, but we can commend it to geometrical students. No statement is made as to how it comes to pass that such a volume was issued under the auspices of the Society named above.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

New Methods of Moving Ordnance

In anticipation of an interesting paper and discussion at the intended meeting of the British Association at Sheffield, a complete set of working models has been prepared at the Floating Dock, North Shields, to explain several new applications of a new method of moving ordnance with ease and rapidity of motion in small space, with economy of time and labour.

The most recent of these improvements is an adaptation of the principles of the tramway and tram car, in making use of the perfectly level surface, and the retaining groove, either on the ship's deck or on the platform of a battery. But instead of flanges on the wheels, that have a tendency to clog and compress dirt into the grooves, and "gag" on the edges, a hanging longitudinal guide-plate projects below the wheels on the inside of the rails; this allows greater freedom of action to the wheel and gives greater security, and in order to attain greater power of resistance to any shock or concussion, the guide plates are strengthened by a cross connecting the plate between them. The gun carriage slide has turn-table pivots on four wheels, that can be placed anywhere; as for the real or imaginary centres of motion at the ends, or centrally or to correspond with the present A B C D pivots of the Royal Artillery, which when in line or parallel or at any angle to each other act as stationary or moving pivots or fulcra for a lever movement of the slide, to turn or move in any direction on perfectly straight lines, as the shortest route between any two points, and also as best adapted for the application of a direct action of any of the usual mechanical motive powers.

North Shields, August 1 GEORGE FAWCUS

"Law of Frequency"

THE term "law of frequency" seems to be used in two distinct senses by mathematical writers. In the ordinary theory the ambiguity leads to little confusion except to beginners; but this is owing to a fortunate, though altogether special, property of the hypothesis on which the theory is based. When we come to investigate other possible theories, it becomes highly important to keep the distinction in mind. Suppose, for clearness' sake, that we have before us a large number of measurements of a single unknown quantity. On examining them we find that a considerable number agree pretty closely with each other, several are more obviously discrepant, while one or two are widely so. Conversely we are led to think of the frequency with which a given measurement occurs as a function of the magnitude of the measurement itself. Denoting this magnitude by x, we may represent the relative frequency of its occurrence by $\phi(x)$. This function is called the "law of freqnency of the measurement x," and it is in this sense that statisticians often use the phrase.

But if we consider all the possible measurements that may be made of the quantity, we see that their number is practically infinite The relative frequency of any proposed measurement becomes therefore infinitesimal, and we must seek for some other expression. This we find by inverting our ideas, as it were, and asking, not "What is the frequency of a given measurement x?" but "What is the probability that a given measurement shall lie between the two very near values x and $x + \delta x$?" Suppose that our particular theory gives us this latter probability as $\psi(x)\,\delta x$. Then mathematicians generally are wont to call $\psi(x)$ "the law of frequency of the measurement x."

A little consideration will show that on one hypothesis only are $\phi(x)$ and $\psi(x)$ necessarily of the same form. This hypothesis is that the arithmetic mean of our fallible measurements is the best value of the quantity measured which we can obtain from them. From this the ordinary law, $\phi(x) \propto e^{-h^2x^2}$, easily follows.

But if the nature of our measurements (or other discrepant magnitudes) be such as to suggest that some other mean is likely to be nearer the truth than the arithmetic mean, we shall find that the forms of $\phi(x)$ and $\psi(x)$ are not the same. It seems, therefore, desirable that a real distinction in the things signified should be marked by a corresponding distinction in the terms applied to them. If it be not too bold a suggestion, might we not "desynonymise" the terms "law of frequency" and "law of facility," keeping the former for the function I have called $\phi(x)$, and the latter for the commoner function I have represented by $\psi(x)$? Carica Papaya

THANKS to Mr. Whitmee for his timely correction of my perhaps too dogmatic assertion as to the seeds of the Papau being rejected by birds, at p. 241. Had I not written off-hand I should have qualified the sentence "the birds however will not touch them," *i.e.* the fruit, by adding "as far as I have observed."

We had flocks of small birds inhabiting the casuerinas and banyans which shaded our sea-side quarters at Rivière Noire, Mauritius; they were mostly small birds such as "bengalis," (*Estrelda amandava*), "senegalis," (*Estrelda astrilda*), "calfats," (*Munia oryzivora*) "tuit-tuits," (*Oxynotus ferrugineus*), cardinals, crithagras, serins, &c., as numerous as finches and sparrows in our English gardens: but never did I see any of these birds, which were as bold and tame as possible, peck at the papaus either on the plants or on the ground; had they been in the habit of doing so I must have observed them. The "martins" or minas of the interior did not trouble us with their visits and noisy chatterings, so I cannot say whether they affect the papau seeds much. It is possible that the "pigeons marrons" and various "tourterelles" may have fed on the papau fruit but I never found any of the seeds in their crops.

The flying foxes, "collets rouges," (*Pteropus Edwarsii*), used to come down in numbers to eat the mangoes of our neighbour, Mons. Genéve; when we used to shoot them on moonlight nights and find them remarkably good eating, but I never knew or heard of their eating the papau, which perhaps they do. The conditions of the Mascarene and Navigator's islands are probably different, as the *Carica* certainly does not spring up as a weed wherever forests are cleared in Mauritius, or Bourbon. The *Carica papaya* figures as a *cultivated* and not an *intrusive* plant in Dr. Charles Pickering's table of observed localities of plants introduced throughout Polynesia; distinguishing for each plant, whether it appears to be native, or spontaneously disseminated, and whether when introduced apparently by the hand of man it has become naturalised or *intrusive*. Certainly Dr. Pickering's work is out of date (1848), and I have not yet seen his new work *Chronological History of Plants* (Trübner, 1879).

Whilst on this subject I may subjoin a paragraph I came across in a number of the *Gardener's Chronicle* about the papau, with which I conclude.

"*Utilisation of the Papaw.*—The peculiar properties of the Papaw (*Carica papaya*) in causing the separation of animal tissues, and thus rendering newly-killed meat tender, is a fact that has been frequently written about and commented upon by travellers. Our contemporary, *The Chemist and Druggist*, suggests, as a 'possible specialty,' the production of some convenient preparation from the tree which should contain the same properties as the leaves, or whether the leaves themselves might be dried and still retain their activity. 'There is no doubt,' they say, 'that a preparation which really embodied

these virtues would be very popular, and that it would soon become one of the necessaries of life, without which no careful housekeeper would allow herself to be left.' It is further pointed out that, as the tree is abundant, and the expense of collecting the leaves would probably be very small, it would be quite worth while to procure a quantity either of the leaves or the juice from the West Indies, and endeavour to obtain a suitable preparation therefrom. If the leaves are brought they might be packed fresh in barrels, which should be filled with salt water—not sea water—and in this way imported; 'or the juice might be expressed from them and saturated with salt, or preserved with benzoic or salicylic acid, and sent over in any convenient vessels. Experience would prove if they would retain these properties when so treated.' These hints may be worth the consideration of some of our readers in countries where the Papaw is abundant."

Anglesey, Gosport, August 4 S. P. OLIVER

The Pacific Salmon

THE reviewer of the U.S. Fisheries' Commission Report, 1875-6, in NATURE, vol. xix. p. 429, pointedly refers with doubt to a statement that "so far as yet observed the adult fish of the Pacific salmon (*Salmo quinnat*) all die after spawning" quoted from a memorandum which I wrote on the subject for the information of the New Zealand Government.

In support of this I would refer to the evidence given in a previous volume of the same reports, 1872-3, p. 191 and elsewhere. This phenomenon, remarkable though it be, is so entirely in accordance with my own observations made during two seasons spent on the upper waters of the Columbia river in 1859-60, and with the opinions I heard expressed by Indians and trappers, that I thought I was justified in mentioning it as a peculiarity of importance.

It may interest your readers to learn that a million of salmon ova of this species have been imported to New Zealand, and that over 700,000 have been hatched and that some 40 rivers have been stocked with the young fish.

Through the great liberality of the American Government at the instance of Prof. Spencer Baird, this invaluable addition to the future food resources of the Colony, has been effected at the cost of only a few hundred pounds to the Colonial Government.

Colonial Museum of New Zealand, Wellington, May 10

A New Spectroscope

IN NATURE, vol. xx. p. 256, a description of M. Cornu's spectroscope for observation of the ultra-violet rays is given.

The lens of the collimator, and that of the observing telescope are said to be composed of a double convex lens of quartz achromatized by means of a plano-concave of Iceland spar, both cut parallel to the optical axis. His prisms are said to be of quartz.

Will you allow me to state that I have used an exactly similar arrangement for the last three years, with the exception that the two prisms are of Iceland spar, which has higher dispersive power. The object glasses were ground and polished for me by Mr. Ahrens of the Liverpool Road. I named the plan about two years ago to my friend Prof. McLeod, and have found it very successful in working. "The Rights of an Animal"

I BELIEVE that when a writer feels himself to have been entirely misrepresented by his reviewer, editorial fairness allows him, at least in such journals as admit correspondence, to set himself right with the reader. The reviewer of my "Rights of an Animal" in NATURE, vol. xx. p. 287, says that, when I claim for animals "the *same* abstract rights of life and personal liberty with man," I use an ambiguous word which casts its shadow over the entire work and makes it unsatisfactory. I should have thought "same" clearly meant "identical." My reviewer says that this cannot be my meaning, because I allow animals to be killed for food and to be worked. He forgets that I have shown how the law of self-preservation overrules the rights both of animals and of men, that it warrants our checking breeding in animals, and that the animals which I allow to be killed or worked were only allowed to come into life for those purposes.

He says that I consider it "immoral to eat shrimps and lobsters." I have indeed asked how we are to defend the killing of "fresh- or salt-water fish or crustaceans," but I have suggested an answer, and have merely added "is this plea sound?" That I leave a question doubtful does not justify a reviewer in saying that I decide it in a particular way.

I will not follow him into an argument between a very sophistical "philosopher" and a very stupid lobster, wherein the former gains an inglorious victory; but, when he in his proper person reproduces, anent another question, one of the philosopher's arguments, and charges me with "the same inconsistency of principle"—because "if man has a moral right to slay a harmful animal *in order to better his own condition*, he must surely have a similar right to slay a harmless animal, *if by so doing he can secure a similar end*"—I must protest that "principle" and "self-interest" are not synonymous, and that a writer who can pen such a sentence is no more capable of reviewing an ethical essay than I of reviewing a book on diamagnetism.

Lastly, he has (even in transcribing my title-page) omitted all mention of my reprints from Lawrence's interesting and very scarce work, and has conveyed to the reader an impression that my book consists of only about 60 pp., an impression very damaging to the chance of the reader buying or even borrowing it. EDWARD B. NICHOLSON

London Institution

Intellect in Brutes

MR. HENSLOW's question (NATURE, vol. xix. p. 433) reminds me of the celebrated carp and bucket of water problem, put by King Charles the Second. He had better have put it thus—"Did ever a person know a dog (or other animal) ring a bell to bring a servant, &c." How can any one tell if an animal goes through any "process of reasoning," save by the results? What will Mr. Henslow say to the following, for which I can vouch, as can others now living? For my part, having watched animals since my childhood, I am fully convinced of their "powers of reasoning" to a certain extent.

Many years ago we lived in Cambridge, in Emmanuel House, at the back of Emmanuel College. The premises were partly cut off from the road by a high wall; the body of the house stood back some little distance. A high trellis, dividing off the garden, ran from the entrance door to the wall, in which was another door, or gate. A portion of the house, a gable, faced the trellis. These particulars are necessary, as you will see.

We were, after some time of residence, extremely troubled by "run-away-rings," generally most prevalent at night, and in rainy, bad, or cold weather, which was a great annoyance to the servant girls, who had to cross the space between the house and the wall, to open the outer door in the latter, and were thus exposed to wet and cold.

The annoyance became so great that at length a cousin and myself, armed with wicked ash saplings, watched behind the trees on "Jesus' Piece," bent on administering a sound thrashing to the enemy, whoever he was, that disturbed our "domestic peace." *Mirabile dictu!* the rings continued, but no one pulled the bell handle! Being a very old house, they were now of course set down to ghosts! but not believing in those gentry, I was puzzled. Chance, however, revealed the originator of the scare.

Being ill I was confined to the wing facing the trellis, and one miserable, blowing, wet day, gazing disconsolately out of the window, espied my favourite cat—a singularly intelligent animal, much petted—coming along the path, wet, draggle-tailed, and miserable.

Pussy marched up to the house-door, sniffed at it, pushed it, mewed, but finding it firmly shut, clambered up to the top of the trellis, some eight or ten feet from the ground, reached a paw over the edge, scratched till she found the bell-wire which ran along the upper rail from the wall to the house, caught hold of it, gave it a hearty pull, then jumped down, and waited demurely at the door. Out came the maid, in rushed Puss. The former, after gazing vaguely up and down the street, returned, muttering "blessings," no doubt, on the ghost, to be confronted by me in the hall.

"Well, Lydia, I have at last found out who rings the bell." "Lard, Master! ye harvent sure*ly*"—she was broad "Zamerzetsheer." "I have; come and see. Look out of the breakfast room window, but don't show yourself." Meanwhile, I went into the drawing-room, where Mrs. Puss was busy drying herself before the fire. Catching her up, I popped her outside of the door, and ran round to my post of observation.

Puss tried the door, and mewed, thinking, probably, some one must be near, and after waiting two or three minutes in vain, again sprang up the trellis, and renewed her attack on the bell-wire, of course to be immediately admitted by the delighted maid, who this time did *not* cross the yard, nor ever again, I fear sometimes to the inconvenience of visitors, if puss was waiting for admission.

Now I think Mr. Henslow will concede that no one ever taught that cat how to ring the bell by *pulling the wire*. To my mind she must have gone through the following process of reasoning:—1. She noticed whenever the bell rang the door opened. 2. In clambering up the trellis to the house-top she accidentally moved the wire, and caused the bell to ring. This probably occurred several times before she noticed it, but having once done so, she repeated it, purposely, whenever she wanted entrance; I have often made her do it for the amusement of friends, by turning her out from her snug nest by the fire on cold or wet days.

I have known dogs shake a door violently to attract attention and be let in. A dear old spaniel of ours, at the Cape, used to rattle the empty bucket if he was thirsty, and then come and look in our faces. My horse will come up from his pasture to the pump in the yard and whinny till some one gives him water. I have known several dogs rear up and place their paws on the old-fashioned "thumb-latch," and let themselves in. Surely all this is "abstract reasoning"? These things are not taught them, and they do not do all of them, even by imitation. I don't go to the pump and whinny, if I want drink! nor rattle a bucket! No! they come by a process of mental reasoning, and I am convinced all animals have it to a certain degree, more or less. I could multiply instances by the page-full, but have already taken up too much space. Among others I could confirm the gnawing of water-pipes by rats to get at the water.

Brit. Consulate, Noumea, May 30 E. L. LAYARD

As a contribution to the doubtless numerous cases in which dogs have recognised the representations in paintings, I put on record the following fact:—

I have in my possession a small picture in which several dogs are represented; a small spaniel was frequently found standing on a chair before the picture and barking at it, and this was the only picture of which he took any notice. P. B. M.

Black Lizards

FROM the interesting letters of Messrs. Giglioli and Ernst it appears that lizards are found of a black colour where, according to received ideas, they ought to be nearly white. How is this anomaly to be explained?

With all due respect to those who have made this subject their study for tens of years, it seems to me that they keep too exclusively to one single proposition, which may be thus enunciated: *An organism is made to prey or be preyed upon.* What I am inclined to maintain is that an unfavourable climate is the common enemy of all, an enemy that must be eluded. If an animal be thrown into a climate too hot, or too cold, it will die if it cannot speedily adapt itself to its altered surroundings. We see a mild case of this adaptation to environment in man himself, the pale-face of temperate zones becoming soon in torrid zones bronzed, and, after a few generations, black. The black dermal covering is therefore clearly the one which is best adapted for extreme heat.

I submit then that here we have the case of the lizards simply stated. On the sandy beaches of Los Roques and Orchila, covered with a very scanty vegetation the pitiless rays of the sun must fall on the lizards in a most uncomfortable manner, to say nothing of the heat reflected and radiated from the ground itself. From the moment the islands were separated from the mainland, a change would commence in the lizards to suit them to their altered position, a change which has resulted in their present wide divergence from the mainland type so far as colour is concerned. WM. ACKROYD

Sowerby Bridge, July 31

Spicula in Helix

THE spicula observed by your correspondent (NATURE, vol. xx. p. 316) lying underneath the albuminiparous gland in some specimens of *Helix aspersa* are probably Spicula Amoris. Their calcareous composition if coupled with a quadrangular outline would establish the fact. PAUL HENRY STOKOE

Beddington Park

Distribution of Black Rat

IT may interest Mr. Middleton to know that in 1866, the black rat was abundant on the top of the Island of Ascension; below, the "House of Hanover" held sway. I counted about a dozen, lying in a manure pit, that had been killed in the farm stables, during the previous two or three days, and was told by a soldier, who did not think them anything out of the way, that "there were plenty of them." E. L. LAYARD

Noumea, May 31

ON THE STRUCTURE OF THE STYLASTERIDÆ: A FAMILY OF HYDROID STONY CORALS[1]

UNTIL the late Prof. Agassiz in 1859 announced his discovery that the Milleporidæ were Hydroids and not Anthozoans, it was confidently believed that all living recent stony corals were most closely allied in their essential structure to the common sea anemones of our coasts. The majority of stony corals still remain under the old category. The beautiful calcareous branched or variously formed objects so familiar as ornaments or as exhibits in museums are nearly all of them formed within the bodies of animals which differ in no important features from the flower-like anemones of our aquariums. The sea anemones have no hard skeleton to support their soft and yielding bodies; the corals differ from them in that they have such skeletons. These are, during the life of the animals of which they form part, entirely embedded within the soft tissues, and only become exposed and appear in the familiar form when the animals are dead and their flesh has been removed from their bones by the action of decomposition or more speedy solution by means of caustic alkalis.

It seems difficult to explain how the popular error by which corals are spoken of as structures built up by coral "insects" arose. It is still perpetuated with considerable misleading detail in some schoolroom books, and it is quite common to meet still with educated persons who regard coral as analogous to honeycomb, and look upon it as built up by the "insects" in much the same sort of way.

Very many corals are solitary or simple, being the skeletons of single animals. As an example may be cited the mushroom-coral, the common chimney ornament, which is the largest known simple coral. This is the skeleton of a single animal comparable with and closely allied to a sea anemone. By far the greater number of forms of corals are, however, compound; that is to say, they are the skeletons of colonies of animals, each comparable to a single mushroom coral but living united together for mutual benefit and with their skeletons fused together to form a common support. Such are for example the various branched Madreporas and other similar forms, and the brain-corals so often brought home from the tropics by sailors.

Until Prof. Agassiz made the discovery above alluded to it was supposed that all stony corals were, as above described, Anthozoan. He found, however, to the astonishment of naturalists, that the corals known as the Milleporidæ were the skeletons of animals allied not to the sea anemones, but to the jelly-fish or Medusæ and the common Hydra of our fresh-water ponds and ditches. The Milleporidæ, of which there are very many species, which, however, fall within but a single genus, Millepora, are either branched and form shrub-like or antler-like masses of various sizes, or occur as irregular rounded lumps, often spreading in their growth over dead corals or other objects, and encrusting them. The Millepores are distin-

[1] The Croonian Lecture, 1878.

guished by the fineness and abundance of the minute pores by which the surfaces of their skeletons are pierced. The animals belonging to these corals had not been examined until they were investigated by Agassiz, and as he was not able to make any extended investigation of their structure, his results were long accepted by many naturalists with considerable hesitation. During the voyage of H.M.S. *Challenger* I studied the structure of several species of Millepora in detail, with the result of confirming Prof. Agassiz's results and yielding a detailed account of the minute structure of these organisms, which is almost complete, excepting with regard to their generative organs, which remain as yet entirely unknown.

In pursuing my observations on corals, I discovered that another family of stony corals, as well as the Milleporidæ, is also Hydroid in structure. This is the family of the Stylasteridæ, an account of the structure of which was selected by the Royal Society as the Croonian lecture for last year, and has just appeared in the new volume of the *Philosophical Transactions.* In the present article I have brought together the principal results of interest which are stated in detail in the lecture.

One of the Stylasteridæ (Allopora) had previously been examined in the living condition by Prof. G. O. Sars, and Sars had suspected that this coral might be Hydroid like the Milleporidæ, but he had been unable to work out the details of the structure of the organism and to prove the matter with certainty. Several observers, the late Dr. Gray, Prof. Verrill, and the Count de Pourtales, had observed the distinctness of the Stylasteridæ, and noticed that there were remarkable peculiarities characterising this family of corals.

The Hydroid stony corals, the Milleporidæ and Stylasteridæ, I have placed in a special sub-order, the Hydrocorallinæ. Though the two families are well distinguished from one another, they show many close resemblances in structure.

Amongst the Hydrocorallinæ there do not exist, as there do amongst the Anthozoan corals, any simple or solitary species; there are no Hydroid corals comparable thus to the mushroom corals, the only forms known are compound colonies. In the case of the Anthozoan corals it seems probable that in the progress of development a simple ancestral form derived from a sea-anemone developed a calcareous skeleton, and that from this solitary form compound corals were derived as subsequent modifications; or, rather, it is not unlikely that several solitary ancestors developed calcareous skeletons independently, and that from each of them different compound forms resulted. In the case of the Hydrocorallinæ, on the other hand, it seems probable that the calcareous skeleton was first developed as a support to already formed colonies, and that no solitary ancestor with a calcareous support preceded them.

Almost all the recent Anthozoan corals belong to the Hexactinia or corals which, like the common sea anemones, have the radially disposed soft structures of their bodies and the corresponding radial plates of their skeletons arranged in multiples of the number six. These Hexactinian Anthozoan corals are termed the Madreporaria. It is a very remarkable f ct that amongst all the vast number of species of compo d Madreporaria known, there seems to exist no instance of a modification of certain of the animals composing the colonies by a subdivision of labour amongst them for the general good to the colony. Amongst Alcyonarian corals and Hydroid corals such a sub-division of labour exists, but for some reason or other such high specialisation seems never to have been attained amongst Madreporaria.

In the case of the Hydrocorallinæ, the subdivision of labour amongst the members of the colonies is carried to a most interesting perfection. It reaches considerable completeness in the Milleporidæ, but in the more advanced Stylasteridæ attains a most elaborate complexity.

In all the Hydrocorallinæ the hard skeleton is very porous, being traversed in all directions by canals which branch and join one another in all directions. Within these canals are lodged corresponding branching and anastomosing tubes composed of soft tissues, which form a complex meshwork within the coral mass, and convey a general circulation common to all the members of the colony. In all the Hydrocorallinæ two kinds of polyps or zooids occur. The more numerous kind are devoid of any mouth or stomach, and act simply as catchers of food for the colony. These are hence termed dactylozooids. The less numerous kind have each a mouth and stomach, and are hence termed gastrozooids; they receive the food from the dactylozooids, and swallow it, and their bases being in direct communication with the general circulation, they nourish with the results of their digestion the dactylozooids and all the component parts of their colony.

In the Milleporidæ the dactylozooids, when expanded, are long and slender, and are provided all along their lengths with short tentacles each of which bears a knob at its end. In the case of the Stylasteridæ, however, the dactylozooids have quite lost their tentacles, and are simply long, slender, tapering bodies, reduced to the aspect of simple tentacles themselves. In the Milleporidæ the gastrozooids are provided with short tentacles round their mouths, and such tentacles are also present in the case of the gastrozooids of most of the genera of Stylasteridæ, the number present varying in the case of each genus. In some genera of Stylasteridæ, however, even the gastrozooids have lost their tentacles, and remain as simple cylindrical digestive sacs; in these instances the entire colonies are devoid of tentacles altogether.

The zooids are lodged within pits or pores on the surfaces of the corals, which are termed gastropores or dactylopores, according to the kind of zooid belonging to them. The gastropores are larger than the dactylopores in correspondence with the size of the respective zooids. In most species of Millepora and several genera of Stylasteridæ the gastropores and dactylopores, intermingled with one another, are scattered irregularly all over the surfaces of the corals; but in one species of Millepora occurring at Tahiti the pores are gathered with some considerable regularity into circular groups, each of which is composed of a single centrally-placed gastropore and a surrounding zone of six or seven dactylopores. In this case the zone of dactylozooids in each group or system ministers to the wants of the single gastrozooid of that system.

The complexity of relations of the zooids advances no further in the case of the Milleporidæ, but in that of the Stylasteridæ many additional complications exist. In several genera (*Allopora*, *Stylaster*, *Cryptohelia*, *Astylus*) the pores occur only in regular circular systems, which are termed cyclosystems. In each of these cyclosystems there is a deep centrally-placed gastropore and a circular zone of from five to upwards of twenty dactylopores. The mouths of the dactylopores, instead of being circular in outline, are drawn out into the forms of long slits, which are disposed in the cyclosystems in a regular radial manner towards the central gastropore. In species in which the dactylopores are numerous and closely packed in the systems, a thin wall only of hard coral skeleton is left intervening between them. Hence each system has closely the appearance of an ordinary Anthozoon coral cup, with its radiating septal plates, and so close is the resemblance that Gray and all earlier observers did not doubt that Stylaster and its allies were essentially similar in structure to the ordinary branching corals, such as Oculina.

The essential difference between a cyclosystem of a Stylasterid and an Anthozoan coral cup is, however, as wide as possible. The radiating plates in the case of the Anthozoan coral are skeletal structures developed

within the body of a single polyp, whereas the so similar-looking radiating plates in the case of the cyclosystem are skeletal plates developed outside the bodies of the numerous component polyps altogether, and separating a number of adjacent polyps from one another. The peculiar radiate form of the cyclosystems of the Stylasterids has no doubt been gradually developed as the result of the constant bending inwards of the dactylozooids in each system to reach their gastrozooid when further and further retracted within its pore. The dactylozooids have thus in course of generations pulled the mouths of their pores out into the form of slits all directed inwards towards the gastropore in each system. In the case of some genera the gastrozooids have carried matters so far that they have ceased to be retracted within their own pores when at rest, but double themselves inwards for safety within the wide mouths of their gastropores. In one genus (Cryptohelia) a further protection is afforded to the zooids by the growth in front of each system of a delicate lid-like lamina of hard coral skeleton, which projects in front, and shields all the zooids when retracted.

In some genera of Stylasteridæ the zooids are not gathered into cyclosystems at all, but various other complications occur. Thus, in some genera there are two kinds of dactylozooids, larger and smaller. The larger and longer, in order to gain more reach in procuring food, are borne at the tips of long spine-like projections of the hard skeletons of the corals, whilst the smaller dactylozooids are lodged in small pores at the bases of these spines where they are in close proximity to the gastrozooids. The larger dactylozooids presumably catch the food, and are helped in delivering it to the gastrozooids by their shorter companions.

As before stated, the mode of generation of the Milleporidæ is as yet unknown, but it is certain that it differs in one important particular from that of the Stylasteridæ. In these latter small cavities, or brood pouches, termed ampullæ, are formed in the hard skeleton of the coral, and in these the generative elements are developed. Each coral stock is of separate sex, all its components being either male or female. The walls of the ampullæ in many cases project above the surfaces of the corals, and are especially prominent in female stocks, since they have in these cases to contain large embryos. In some specimens of Stylasteridæ the ampullæ are very conspicuous to the naked eye, looking like small convex blisters closely packed on the surfaces of the coral branches. They are particularly well marked in the case of female stocks of species of Distichopora, which are thus especially serviceable for class demonstration, and when the generative function of the ampullæ is premised, afford evidence at a glance of the hydroid nature of the Stylasteridæ. The ova are developed within the ampullæ to the condition of mature planulæ, when they are set free by the gradual thinning and final rupture of the ampullar walls and swim off to start fresh colonies. It is highly probable that the masses of tissue from which the ova are developed, and which protect them during growth, are representatives of polyps, which have, like the dactylozooids, lost their mouths, and have come by restriction of function to be mere egg-bags as it were.

In all the Stylasteridæ, even those with very complex cyclosystems, there is a complete circulatory connection between the different systems and all parts of the colony, as well as amongst the components of each system. Thus in these complex mutual benefit associations, certain members of the colonies catch the food, but do not eat it, others receive it from them and nourish the whole colony thereby, whilst others again neither catch food nor eat it, but devote themselves entirely to the production and rearing of the young.

The ancestral forms from which the Hydrocorallinæ have been developed must have been colonies closely similar in essential structure to their present descendants, but with all their component zooids provided with mouths and generative organs, all alike catching food and digesting it, and possibly all taking their share in the production of young. In such colonies further development may be conceived of as having arisen by either of two processes. All the zooids may have become gradually modified, so that each performed only one function and thus had certain of its structures aborted to fit it for this special end. If such be the history of the development of the Hydrocorallinæ then the dactylozooids are to be looked on as they have been regarded throughout this paper as representatives of zooids which in the ancestral condition were provided with a mouth and stomach, but in which these structures as well as the generative structures have become rudimentary by disuse. Similarly in the case of the gasterozooids the functions of prehension have to a large extent been lost, and the zooids have become, in some cases, mere stomachs.

On the other hand the view may be taken that the gastrozooids alone represent the original zooids of the ancestral colony. They remain, having lost their generative organs and to a greater or less extent their prehensile ones because additional zooids have been formed by budding in order to provide for the wants of the colony in these particulars. On this view the generative zooids and dactylozooids were originally budded out in the condition in which they now exist or in one not so complete as it is at present, nor so perfectly adapted to their present function. On this view they have lost no structure by disuse, but have rather advanced in complexity with development but only in their own specialised direction.

The former view of the antecedent history of the suborder Hydrocorallinæ has been here adopted, because the presence of several structures which occur as rudiments in connection with the dactylozoids and generative zooids, but which are fully developed in connection with the gastrozooids, seem to bear out this conclusion. As examples may be cited the calcareous styles which gave the name to the family Stylasteridæ. These styles are small projections of the hard skeletons of the corals which support the gastrozooids within their pores. In several genera rudimentary styles are found to occur in connection with the dactylozooids.

The Stylasteridæ, in the complexity of their compound stocks, form an interesting parallel to the Siphonophora. In the Siphonophora the several components of the compound organisms are by the best authorities regarded not as individual zooids, but as portions of the organisms which, being budded out, tend in their growth to assume more and more the form of individuals. The question is to some extent one of nomenclature, but it must not be forgotten that though the diverse elements composing the organism in the case of the Siphonophora may seem closely paralleled by those of which that of a Stylasterid is made up, the past history of the two organisms may be very different. In the one case an ancestral already compound organism may have gradually modified its similar zooids to subserve division of labour, whilst in the other a simple ancestor may have gradually developed a similar compound organism by throwing out buds of various forms, which have come more or less to approach itself in complexity. H. N. MOSELEY

IRIDO-PLATINUM

THE volume of the *procès-verbaux* of the International Commission of Weights and Measures published in Paris last year,[1] contains, among other matter of much value, an interesting appendix by MM. Sainte-Claire Deville and Stas, who were requested by the Commission to ascertain the composition of the platinum-iridium alloy employed in the preparation of the rules and cylinders

[1] Gauthier-Villars. Paris, 1878.

destined to serve as the International Prototype Standards. Their investigations are set forth at great length, and analytical chemistry is thus enriched by an elaborate memoir, in every way worthy of its distinguished authors. The alloys of platinum iridium, of which these standards are made, was furnished by Mr. George Matthey, of the well-known firm of Johnson, Matthey, and Co., and, in the April number of the *Annales de Chimie*, there is a paper by MM. Deville and Mascart, describing the experimental determinations of the various physical constants of the metal of which the Règle Géodésique is made. We cannot do better than quote their words as indicating the care and skill bestowed by Mr. Matthey in the preparation of this standard: "En fabriquant un pareil alliage avec une telle pureté, M. Matthey a résolu un problème de métallurgie des plus difficiles et des plus compliqués. On ne peut s'imaginer, à moins qu'on ne connaisse dans tous leurs détails les procédés si pénibles employés à la purification de l'iridium et même du platine, combien il a fallu d'intelligence, de patience et de dévouement à la Science pour réussir dans une pareille œuvre." [1]

As the matter is of much importance, a paper recently communicated to the Royal Society by Mr. G. Matthey possesses special interest, as in it he describes the methods employed for preparing the metals in a state of purity. The following is an abstract:—

"The six metals (of which platinum is the chief) usually found more or less in association, present characteristics of interest beyond their metallurgical utility, which are, perhaps, worth alluding to. It is, for instance, a curious fact that the group should consist of three light and three heavy metals, each division being of approximately the same specific gravity—the heavier having (in round figures) just double the density of the lighter series.

Thus we find osmium, iridium, platinum forming the first division, of the respective specific gravities of 22·43, 22·39, 21·46; whilst ruthenium, rhodium, and palladium are represented by the figures 11·40, 11·36, 11, the average densities of the heavy and light divisions thus being respectively 22·43 and 11·25.

But a more interesting and important classification is what I may designate as a first and second class series, from the more important view of their relative properties of stability. Thus platinum, palladium, and rhodium form the first or higher class, not being volatilisable in a state of oxide; iridium, osmium, and ruthenium forming the second or lower class, their oxides being more or less readily volatilised.

The oxide of iridium is affected at 700° to 800° C., and entirely decomposed at 1,000°, whilst osmic and hypo-ruthenic acids are volatilised at the low degree of 100°, the latter exploding at 108°. The chlorides of these metals can be sublimed at different temperatures (as also the protochloride of platinum).

Platinum

The preparation of this metal in a state of purity is an operation of extreme delicacy. I commence by taking ordinary commercial platinum; I melt this with six times its weight of lead of ascertained purity, and, after granulation, dissolve slowly in nitric acid diluted in the proportion of 1 volume to 8 of distilled water. The more readily to insure dissolution, it is well to place the granulated alloy in porcelain baskets such as are used in the manufacture of chlorine gas for holding the oxide of manganese. When the first charge of acid is sufficiently saturated, a fresh quantity should be added until no more action is apparent; at this stage the greater part of the lead will have been dissolved out, together with a portion of any copper, iron, palladium, or rhodium that may have been present. These metals are subsequently extracted from the mother-liquors, the nitrate of lead by crystallisation, and the remaining metals by well-known methods.

[1] *Ann. de Chim. et de Phys.*, 5me Série, t. xvi., April, 1879.

The metallic residue now obtained will be found in the state of an amorphous black powder (a form most suitable for further treatment), consisting of platinum, lead, and small proportions of the other metals originally present—the iridium existing as a brilliant crystalline substance insoluble in nitric acid. After digesting this compound in weak aqua regia, an immediate dissolution takes place of the platinum and lead, leaving the iridium still impure, but effecting a complete separation of the platinum.

To the chloride of platinum and lead after evaporation is added sufficient sulphuric acid to effect the precipitation of the whole of the lead as a sulphate, and the chloride of platinum, after dissolution in distilled water, is treated with an excess of chloride of ammonium and sodium, the excess being necessary in order that the precipitated yellow double salt may remain in a saturated solution of the precipitant. The whole is then heated to about 80°, and allowed to stand for some days; the ammonio-chloride of platinum will settle down as a firm deposit at the bottom of the vessel, whilst if any rhodium, as is generally the case, is present, the surface liquor will be coloured a rose tint, occasioned by a combination of the salts of the two metals.

The precipitate must be repeatedly washed with a saturated solution of chloride of ammonium and subsequently with distilled water charged with pure hydrochloric acid. This is necessary for its purification. The small quantity of the double salt which will be taken up and held in solution is of course recovered afterwards. Rhodium may still exist in the washed precipitate, which must therefore not be reduced to the metallic state until its separation is completed, and this is best effected by mixing with the dried compound salts of chloro-platinate and chloro-rhodiate of ammonia, bi-sulphate of potash with a small proportion of bi-sulphate of ammonia, and subjecting to a gradual heat brought by degrees up to a dull red in a platinum capsule, over which is placed an inverted glass funnel. The platinum is thus slowly reduced to a black spongy porous condition freed from water, nitrogen, sulphate of ammonia, and hydrocloric acid, the rhodium remaining in a soluble state as bi-sulphate of rhodium and potash, which can be dissolved out completely by digesting in boiling distilled water; a small quantity of platinum will have been taken up in the state of sulphate, but is regained by heating the residue (obtained on evaporation) to redness, which reduces it to the metallic condition, the rhodium salt remaining undecomposed.

By the method above described the platinum is freed not only from rhodium, but from all other metals with which it may have been contaminated, and is brought to a state of absolute purity, of the density 21·46, the highest degree obtainable.

Iridium

In practice, the purest iridium which can be obtained from its ordinary solution (deprived of osmium by long boiling in aqua regia and precipitated by chloride of ammonium) will almost invariably contain traces of platinum, rhodium, ruthenium, and iron.

I fuse such iridium in a fine state of division with ten times its weight of lead, keeping it in a molten state for some hours, dissolve out the lead with nitric acid, subject the residue to a prolonged digestion in aqua regia, and obtain a crystalline mass composed of iridium, rhodium, ruthenium, and iron, in a condition suitable for my further treatment. By fusion at a high temperature with an admixture of bi-sulphate of potash, the rhodium is almost entirely removed, any remaining trace being taken up together with the iron in a later operation. The iridium so far prepared is melted with ten times its weight of dry caustic potash, and three times its weight of nitre, in a gold pan or crucible; the process being prolonged for a considerable time to effect the complete transformation of

the material into iridiate and rhuthenate of potash, and the oxidation of the iron; when cold, the mixture is treated with cold distilled water. The iridiate of potash of a blue tinge will remain as a deposit almost insoluble in water, more especially if slightly alkaline, and also the oxide of iron.

This precipitate must be well washed with water charged with a little potash and hypochlorite of soda until the washings are no longer coloured, and then several times with distilled water.

The blue powder is then mixed with water strongly charged with hypochlorite of soda, and allowed to remain for a time cold, then warmed in a distilling vessel, and finally brought up to boiling point until the distillate no longer colours red, weak alcohol acidulated with hydrochloric acid.

The residue is again heated with nitre and potash water charged with hypochlorite of soda and chlorine, until the last trace of ruthenium has disappeared.

Further, to carry out the purification, the blue powder (oxide of iridium) is re-dissolved in aqua regia, evaporated to dryness, re-dissolved in water, and filtered.

The dark-coloured solution thus obtained is slowly poured into a concentrated solution of soda and mixed with hypochlorite of soda, and should remain as a clear solution without any perceptible precipitate, and subjected in a distilling apparatus to a stream of chlorine gas, should not show a trace of ruthenium when hydrochloric acid and alcohol are introduced into the receiver. In this operation the chlorine precipitates the greater part of the iridium in a state of blue oxide, which, after being collected, washed, and dried, is placed in a porcelain or glass tube, and subjected to the combined action of oxide of carbon and carbonic acid obtained by means of a mixture of oxalic with sulphuric acid gently heated.

The oxide of iridium is reduced by the action of the gas leaving the oxide of iron intact, the mass is then heated to redness with bi-sulphate of potash (which will take up the iron and any remaining trace of rhodium), and after subjecting it to many washings with distilled water, the residue is washed with chlorine water to remove any trace of gold, and finally with hydrofluoric acid, in order to take out any silica which might have been accidentally introduced with the alkalies employed or have come off the vessels used.

The iridium after calcination at a strong heat in a charcoal crucible, is melted into an ingot.

Alloy of Iridio-Platinum

Operating upon a charge of 450 ounces of platinum and 55 ounces of iridium, I commenced by melting these metals together and casting into an ingot of suitable shape, which I then cut into small pieces with hydraulic machinery. After re-melting and retaining in a molten condition under a powerful flame of oxygen and common gas for a considerable time, I re-cast and forged the mass at an intense white heat under a steam hammer, the highly-polished surfaces of which were cleaned and polished after each series of blows—when sufficiently reduced the alloy was passed through bright polished steel rollers, cut into narrow strips, and again slowly melted in a properly-shaped mould, in which it was allowed to cool. I thus obtained a mass of suitable shape for forging, perfectly solid, homogeneous, free from fissures or air-holes, and with a bright and clean surface.

A piece cut from the end of a mass so prepared, was presented to the French Academy of Science, and gave the following results:—

Weight in air	116·898 grms.
,, water	111·469 ,,
Showing a density of	21·516 ,,

thus proving that the necessary processes of annealing at a high temperature had caused it to resume its original density.

The analysis gave—

	1	2
Platinum	89·40	89·42
Iridium	10·16	10·22
Rhodium	0·18	0·16
Ruthenium	0·10	0·10
Iron	0·06	0·06
	99·90	99·96

From which is deduced:—

	Proportion.	Density at zero.	Volume.
Iridio-platinum at 10 per cent.	99·33	21·575	4·603
Iridium, in excess	0·23	22·380	0·010
Rhodium	0·18	12·000	0·015
Ruthenium	0·10	12·261	0·008
Iron	0·06	7·700	0·008
	99·90		4·644

Density at zero, calculated after No. 1 analysis	21·510
Density at zero, calculated after No. 2 ,,	21·515

which coincide perfectly with the practical results obtained."

MM. Deville and Mascart find the coefficient of dilatation to be from 0° to 16° C. 0·00002541.

As we have already pointed out, work on which the accuracy of standards depends is of the highest importance, and Mr. Matthey is therefore to be congratulated on the success of his labours.

THE INFLUENCE OF THE TRANSVERSE DIMENSIONS OF ORGAN PIPES ON THE PITCH

IN NATURE, vol. xix. p. 172, Mr. Ellis gives, on the authority of M. Cavaillé-Coll, a rule determining a point of some interest in regard to organ-pipes. All those who are accustomed to organs know that the theoretical rule which makes the vibration-number of the note sounded vary inversely as the length of the pipe, does not hold correctly in practice, as the pitch is influenced by the *transverse dimensions*. A pipe of "large scale," *i.e.*, of large diameter, will speak a lower note than one of "small scale," the length of the tube being in both cases the same. I am not aware that this fact has been explained in acoustical works, or any rule given for the variation.

Mr. Ellis's formula provides for this, so far as cylindrical pipes are concerned, and he has found it to agree well with experiment. There is a misprint in his equation, which at first sight renders it somewhat obscure, and in correcting this I will venture to present M. Cavaillé-Coll's investigation more completely, as it was expressed by him in a paper presented to the Academy of Sciences many years ago, and a copy of which he was good enough to give me.

After calling attention to the theoretical rule, he remarks that the departure from it is due to the influence of the *mouth* of the pipe, *i.e.*, the rectangular opening at the lower end of the tube. He made many experiments to determine the effect of this, and came at length to the result that in open pipes of rectangular section the *effective length of the pipe* was equal to the *length of the sound-wave* due to its note [or the half wave-length according to our mode of calculation] *diminished by twice the internal depth* of the tube. By the "depth" is meant the transverse dimension from front to back; the other transverse dimension, the *width*, appearing to be of no consequence.

Thus, if S represent the velocity of sound, V the number of vibrations per second (*single* ones, according to the French mode of calculation), L the length of the pipe, taken from the lower edge of the mouth to the end of the tube; and P the internal transverse depth, then—

$$L = \frac{S}{V} - 2P.$$

M. Cavaillé-Coll gives two examples of applications he made of this formula :—

1. A wood pipe sounding what is called 4-foot C, 264 [single] vibrations per second at the normal French pitch, and having a depth of 8 centimetres, was found to have a length of $1^{m} \cdot 13$. Taking the velocity of sound at 10° to 15° C. to be 340 metres per second, the equation would give—

$$\frac{340}{264} - 0{\cdot}16 = 1^{m}{\cdot}128,$$

differing only 2 millimetres from that actually found.

2. The large 32-foot pedal pipe of the organ of St. Denis was at first cut to a length of $9^{m} \cdot 566$, the internal depth being $0^{m} \cdot 48$. The number of single vibrations per second was intended, according to the standard pitch, to be 33, according to which the equation gave—

$$\frac{340}{33} - 0{\cdot}96 = 9^{m}{\cdot}36$$

as the calculated length. This showed the pipe to be too long, which proved to be the fact, the note being too flat. An opening was then made to reduce the effective length to that given, when the pipe was found to be in perfect tune.

In applying the formula to *cylindrical* pipes, M. Cavaillé-Coll found the same law obtain; allowing for the difference in shape, and for the flattening of the pipe necessary to form the mouth properly, he considered that the mean depth was about equal to five-sixths the diameter, or—

$$P = \frac{5}{6} D.$$

Substituting this in the above equation it becomes, for cylindrical pipes—

$$L = \frac{S}{V} - \frac{5}{3} D.$$

Taking now the mean velocity of sound given by M. Cavaillé-Coll, namely, 340 metres or 1115 feet per second; putting the dimensions of the pipe in inches, and altering V to represent the number of *double* vibrations per second, according to our English custom; we obtain, finally, for cylindrical pipes—

$$L = \frac{6690}{V} - \frac{5}{3} D; \text{ or}$$

$$V = \frac{20070}{3L + 5D}.$$

Mr. Ellis's rule is—

$$V = \frac{20080}{3L + 5V}.$$

the letter V, however, in the denominator being clearly a misprint for D.

The foregoing rules, it must be stated, apply to pipes *open at the end*, which constitute the great bulk of those in an organ. WILLIAM POLE

GEOGRAPHICAL NOTES

THE letter from Sir Rutherford Alcock in yesterday's *Times*, announcing the death of Mr. Keith Johnston, will be received with surprise and sincere regret. As our readers know, Mr. Johnston was leading the Geographical Society's expedition from Dar-es-Salaam to the north end of Lake Nyassa, and, if possible, thence to Tanganyika. A start was made on May 14, and now the sad news comes that the young leader died of dysentery on June 28, at Berobero, about 130 miles inland. Mr. Johnston came of a famous geographical house, and had already done good exploring work in South America. He was enthusiastic on the matter of African exploration, and was well qualified to carry it out in a scientific method. His death is a real loss to scientific geography. We are glad to learn that the expedition will be continued under the leadership of Mr. Thomson, the geologist who accompanied Mr. Johnston.

IT is with great pleasure we learn from a letter of Dr. G. Nachtigal to the editor of Petermann's *Mittheilungen*, that the announcement of Dr. G. Rohlfs' retirement from the leadership of the expedition of the German African Society was premature. He did express a wish to resign, but has since been able to overcome all initiatory difficulties, and left Benghazi with his followers on July 4, and it is hoped will be able to reach Abesh, the chief town of Wadai, about the middle of next month. Dr. Nachtigal's account of his own great exploring work in North and Central Africa from 1869 to 1874 has just been published in Berlin.

AT the last sitting of the Paris Geographical Society, M. Paul de Soleillet explained his scheme for putting Timbuctu in communication with the Atlantic. A railway must be made from Dakkar, on the Atlantic coast and St. Louis, the head city of French Senegal. This work will be begun next winter. The Senegal must be rendered navigable from St. Louis to Bafoulabé, and a canal constructed from Bafoulabé to Bamakou, on the Niger. These projects having been adopted by the High Commission, the Survey for the canal will begin immediately. The Niger is navigable without works of any description from Bamakou to Timbuctu and other places below for a distance of 1,500 miles. The aggregate expense required for the whole of the work is estimated at a million sterling, and the number of people placed in close connection with French Senegal thirty-seven millions. A M. Fourreau has sent a letter to the President of the Society stating that he, with two friends, had established a farm in Oued Bish, about 150 miles southward of Biskra, in the direction of the intended Transaharian Railway *viâ* Biskra. The exploration committee of the Saharan Railway Commission has recommended the Government to send out M. Soleillet to visit the unexplored regions between 15° and 25° N. lat.

TAKEN as a whole, the August number of the Geographical Society's monthly periodical appears to be the best that has been issued. The papers are Major Serpa Pinto's notes of his journey across Africa ; Mr. McCarthy's "Across China, from Chinkiang to Bhamo;" and the late Capt. R. R. Patterson's notes on Matabeli-land. The map of South Africa, accompanying Major Pinto's notes, is particularly interesting, as it embodies a good deal of original information. The geographical notes are unusually full and varied, and we are glad to observe that greater attention is being paid to this most essential department of a geographical magazine. Since the note on Major Tanner's exploratory visit to Kafiristan was written, news has unfortunately arrived that ill-health has compelled that officer to return to India. There is a useful summary of Dorandt's report, published by the Russian Geographical Society, on his astronomical and magnetic observations on the Lower Oxus, and of Mr. Hillier's account of his journey in North China at the beginning of this year. Climatology also claims a place among the notes. The remainder of the number is occupied with a report of the evening meetings, the proceedings of foreign societies, and notes on new books and maps.

NEWS has just been received at Copenhagen from the scientific expedition which sailed for Greenland in the *Ceres* on March 29 last. The expedition, which consists of two naval officers, MM. Jansen and R. Hammer, and a student of polytechnics, M. Kornerup, reached the Holsteinborg Colony, in Greenland, on April 30, and at once proceeded with their investigation and measurement of the coast and fjords between Holsteinborg and Egedesminde. They left the neighbourhood of Holsteinborg on May 15, travelling in small Greenland boats. From that date to the end of August, when they hope to reach Egedesminde, the explorers will have to camp in their boats or on the rocky shore. However, the summer nights are bright in those latitudes, and the expedition is well equipped with all necessaries.

ELECTRICAL CLOCKS AND CLOCKWORK

IN the year 1843 an electrical pendulum which forms the basis of nearly all succeeding systems of electrical clockwork, was patented by the late Alexander Bain. (See Fig. 1.)

The bob of the pendulum, C, consists of a coil of insulated wire. One end of the wire passes to the axis of the tumbler A T, the other, through the suspension spring S, to the plate P_1. P_1 P_2 are plates, say of zinc and carbon, and are sunk in the earth to form the battery. From P_2 a wire W_2 proceeds to N. MM is a horse-shoe magnet. Whilst AT leans against N, a current is passing, and C is magnetic. C has its − and + poles facing the + and − poles of the horse-shoe magnet. Consequently the pendulum is driven to the left, but when it reaches a certain point, AT topples over, the current ceases, and the pendulum returns. The pendulum now proceeds on its swing to the right, but on approaching the limit of its oscillation, overturns AT again, the current is renewed, and the pendulum again propelled to the left. This action automatically repeats itself. Mr. Bain placed within the circuit of his pendulum any number of electrical dials. Fig. 2 shows the mechanism of these. C is a coil either in the line of W_1 or W_2. When a current passes C becomes magnetic, and oscillates between the magnets MM. At every swing of C a tooth, T_1, of the wheel is gathered up by the detent DD. The click, KK, by holding a tooth, T_2, prevents the wheel returning whilst D is passing to the right.

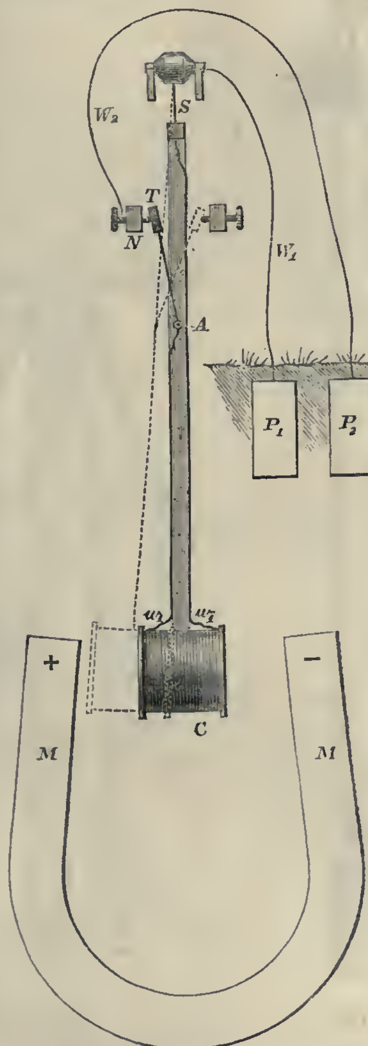

FIG. 1.

The impulse on Mr. Bain's pendulum varied with the power of his battery, a condition fatal to good time-keeping. In 1849 Mr. Shepherd patented a system in which the current was employed to lift a slight weight or spring. The fall of this propelled his pendulum, and gave an impulse quite independent of any variation in the power of his battery. Fig. 3 shows one of his plans.

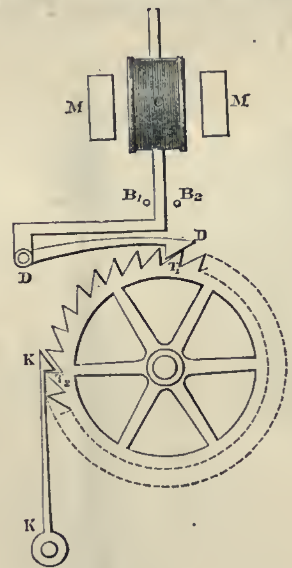

FIG. 2.

PP is the pendulum, W a weight, mounted on a lever WCA. WCA can move about a centre C, and is at present prevented from turning by the catch SS. When PP swings to the right, the lower screw in PP passes under E (see side view Z) and frees WCA. WCA, under the weight of W, propels the pendulum to the left till stopped by a banking B. PP moves on and makes contact with T, whereupon a current passes, M_1 M_2 become magnetised, and attract LL, the vertical arm of which lifts WCA over the catch SS again. When PP leaves T the current ceases, and LL is carried back to its old position by the action of the spring R.

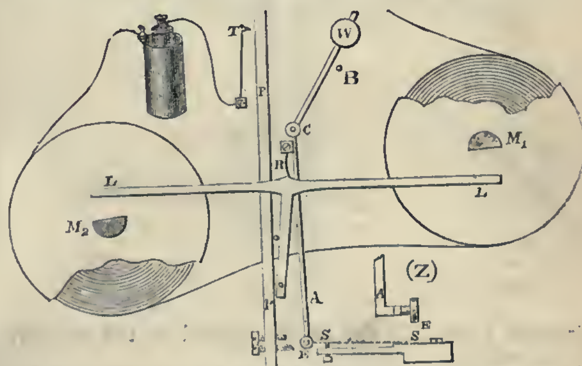

FIG. 3.

Mr. Bain's and Mr. Shepherd's are the leading types of electrical clocks properly so called, that is to say, of clocks which keep themselves going by electricity. But it

is scarcely worth while to use electricity when you can get gravity more cheaply. And do what you will, you can never absolutely rely on getting your current when you want it. For these reasons purely electrical clocks are very seldom used, it being found better to do whatever electrical work is required, by an ordinary clock with galvanic contact apparatus affixed. But though electrical clocks pure and simple have not made much progress, the system of *controlling* a quantity of indifferent clocks from one good one has. This principle was invented by Mr. Jones, of Chester, and Fig. 4 shows it.

(3) is the pendulum of the controlling clock, and (2) that of a controlled clock; (1) is a side view of (2). C, the bob of (2) is a hollow coil of insulated wire, and swings over two magnets, M_1 M_2, which have their similar poles facing each other. The ends of the wire forming C are carried up the pendulum, pass respectively through S_1 S_2, and terminate in T_1 T_2. T_1 is joined to T, which crowns the pendulum of the controlling clock, and T_2 is in connection with both N_1 N_2, the contact springs of the same. Both N_1 N_2 have their respective batteries, B_1 B_2, but with opposite poles towards J; so that if C is magnetised in one

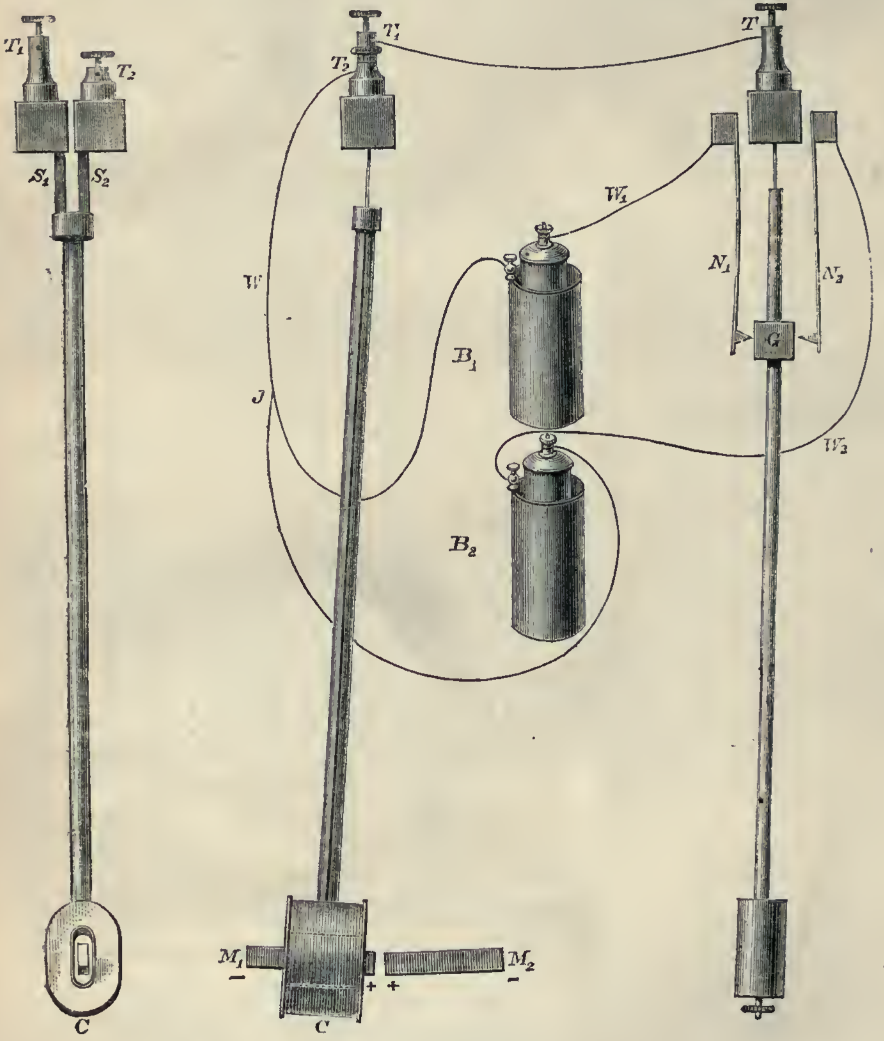

FIG. 4.

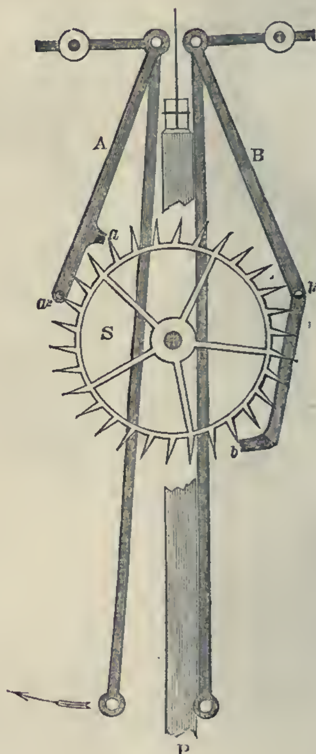

FIG. 5.

direction by one, it will be magnetised in the opposite by the other.

Suppose (2) has a tendency to lag as compared with (3). When (3) approaches the extremity of its swing, G meets N_1, a current passes, C is magnetised and is pulled on smartly. When G leaves N_1, the current ceases. G goes to meet N_2, then C, which is now over M_2, is again magnetised, but in the reverse direction. M_2 being also reversed as regards M_1, C, if behind, is pulled on again. Should (2) be in front of (3) its motion would be checked. A great many clocks can by this method be kept swinging in unison together.

Mr. Ritchie, of 25, Leith Street, Edinburgh, has patented an ingenious modification of the above. He places in the circuit of his controlling clock not other clocks, but pendulums. These he drives in just the same way as Mr. Jones controls his, and each pendulum works a train of wheels which move hands. Mr. Ritchie's are really electrical dials, but they have this great advantage, that should the current fail, as currents are apt to occasionally, the momentum of the pendulums is sufficient to keep the dials moving for a short time independently of it. The method by which the pendulums drive the wheel work is interesting (see Fig. 5).

A and B, the pallets, swing loose. S, the escape wheel, is now being held against a_2, a stop on A, by the weight of

B, which is pressing the tooth b. B has been deposited on b by the pendulum P, which is swinging to the left. Presently the pendulum lifts the vertical arm of A, and unlocks the wheel. The wheel moves on, but B falls, and the stop b_2 on B catches the tooth which is just above it. The pendulum continues its swing, and on returning, deposits A on the next succeeding tooth to a. It then proceeds to B, and continues the performance as before.

It is desirable that you should know that all your controlled or driven clocks are performing properly. In the circuit, alongside the standard clock, a galvanometer is

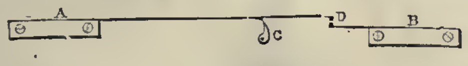

FIG. 6.

placed, and each of the controlled or driven clocks is fitted with the following mechanism (see Fig. 6).

A D, D B are two springs through which the current passes. C is a lifter upon the axis of the escape wheel of one of the controlled or driven clocks. Every minute C comes round and breaks the circuit for one second, and anybody standing at the controlling clock, knows when this happens by the needle of the galvanometer remaining stationary. We arrange, for instance, that clocks A, B, C, D shall cut out respectively the 3rd, 9th, 15th, and 40th seconds, and if these seconds are regularly cut out, we know that our controlled clocks are running with the standard.

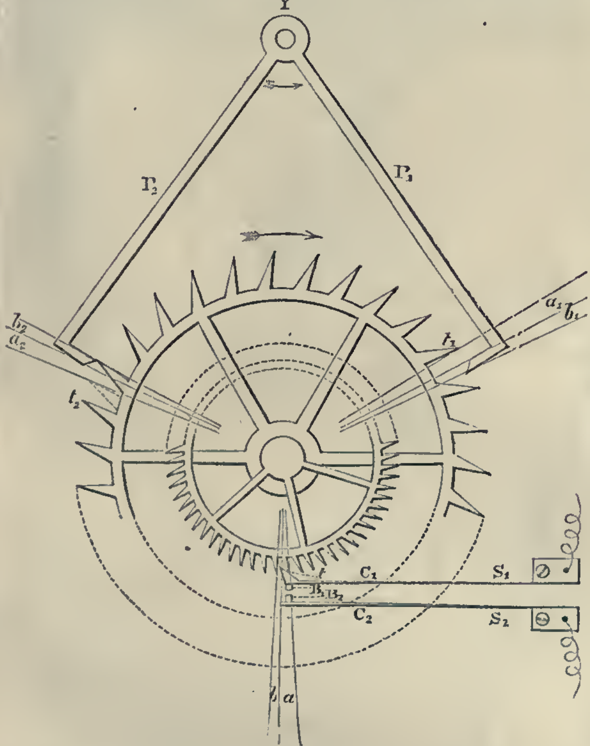

FIG. 7.

It is a matter of importance that the system of making electrical contact shall disturb the pendulum as slightly as possible. The method described above (by the two springs N_1 N_2) would scarcely suffice, when the most accurate timekeeping was required. The standard sidereal clock at Greenwich has a jewelled pin in the crutch rod which in passing zero presses two weak springs together. A better plan (Mr. Hartnup we are informed had also previously used it) seems one which has just been constructed by Messrs. Dent for some other work. In this it would appear that the resistance of the contact springs cannot affect the pendulum at all; because the springs are lifted during the drop of the escape wheel from one pallet to the other (see Fig. 7).

A tooth has just passed from the impulse face of the

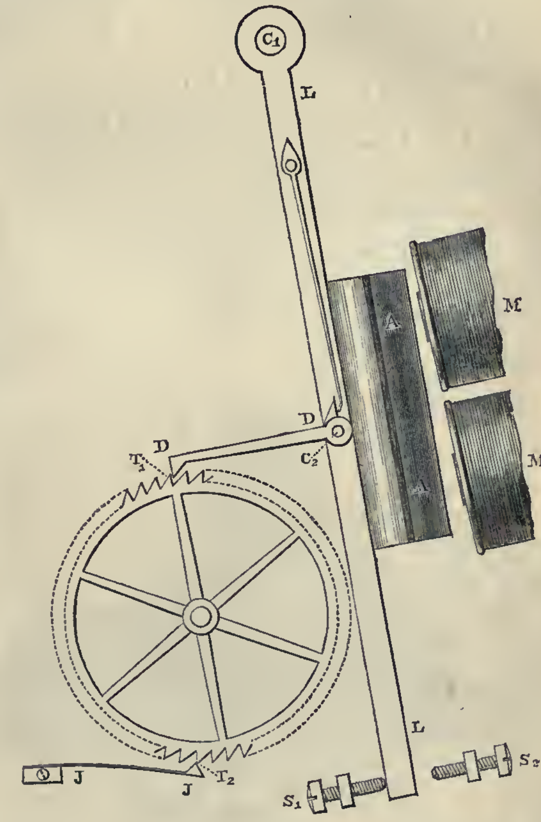

FIG. 8.

pallet P_2; t_1 now falls through the angle a_1 on to the dead face of the pallet P_1. *During this interval* the tooth t of the smaller wheel mounted on the same axis as the escape

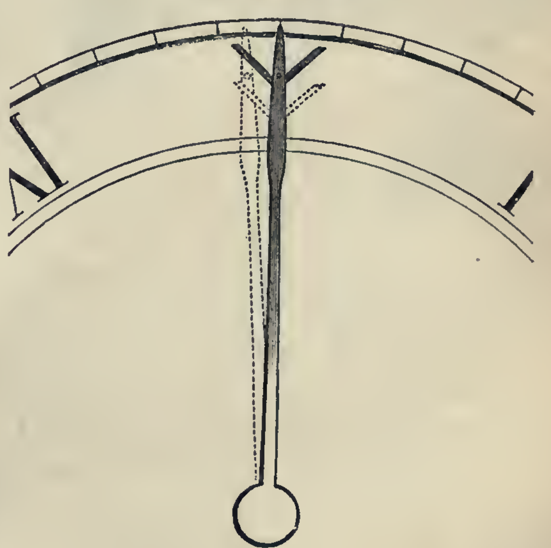

FIG. 9.

wheel lifts the contact spring C_1 S_1 against the contact spring C_2 S_2, and the current passes. It will be seen that when the tooth t_1 goes on to give impulse to the pallet

P_1 through the angle b_1, the tooth t has allowed the springs to drop, and that it travels through its corresponding angle b perfectly undisturbed. The motion of the tooth t_2 can easily be traced from the drawing. Careful workmanship is required to carry out this method properly, as the angles a, a_1, a_2 ought to be made much smaller than in the drawing.

Fig. 8 shows some electrical dial work.

M M are coils, A A is an armature, L L a lever turning about C. D D is mounted on L L and kept in position by a spring. J J is a jumper. As soon as a current ceases, L L, which has been attracted by M M, falls, and D D drives forward a tooth, T_1. When D D reaches the limit of its thrust, the point of J J just gets round the corner of T_2, and drives on T_2, makes it jump a little further. The jumper seems a better arrangement than the usual ratchet.

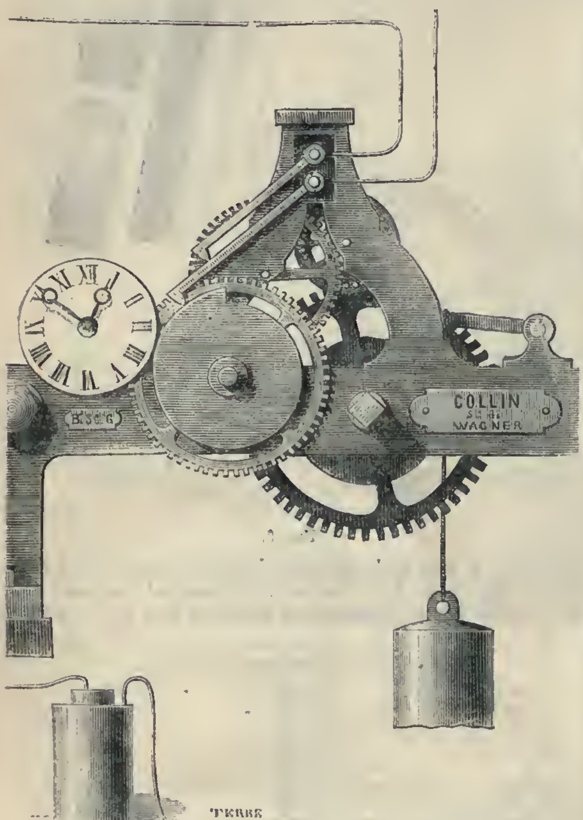

Fig. 10.

It has become popular of late to set the hands of indifferent clocks by electricity. This plan was proposed by Mr. Bain as far back as 1843, and his method of accomplishing it was as follows (see Fig. 9). Behind the minute hand at 12 o'clock is placed a V, and in the minute hand is a pin. Every hour a current from the standard clock raises the V. Should the hand be fast or slow it is immediately forced to the hour, for the pin is bound to find its position at the bottom of the V. A plan similar in operation has recently been patented by Messrs. Barraud and Lund. It is fully described in NATURE, vol. xix. p. 55.

Another method of correcting clocks was invented by M. Collin, Chevalier of the Legion of Honour, and has been largely made use of by him. Fig. 10 shows his standard clock, and Fig. 11 the clock to be corrected; the latter is regulated to gain a second or two per hour. A few minutes before each hour the lower of the two detents in Fig. 10 is lifted against the upper, and a current passes. As regards the clock, Fig. 11, the current avoids

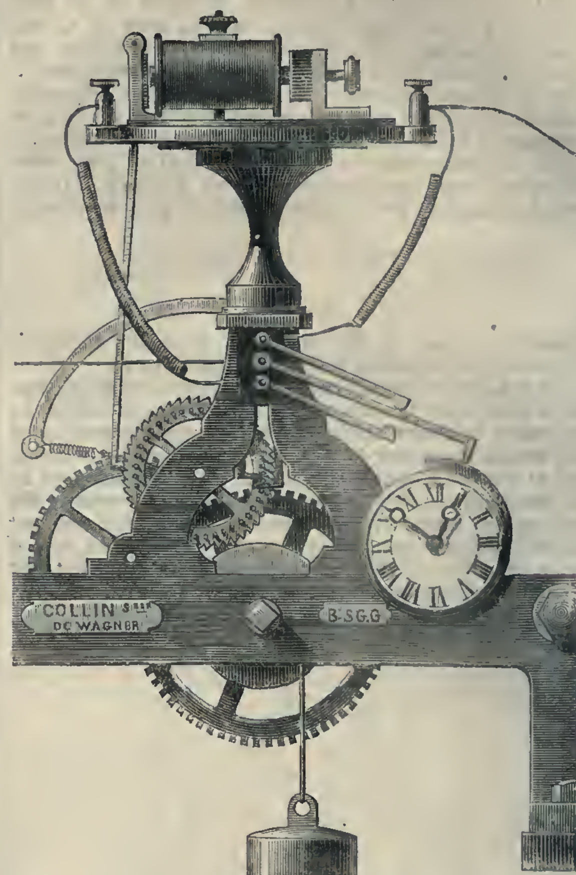

Fig. 11

for the present the coil mounted on the top of it. When

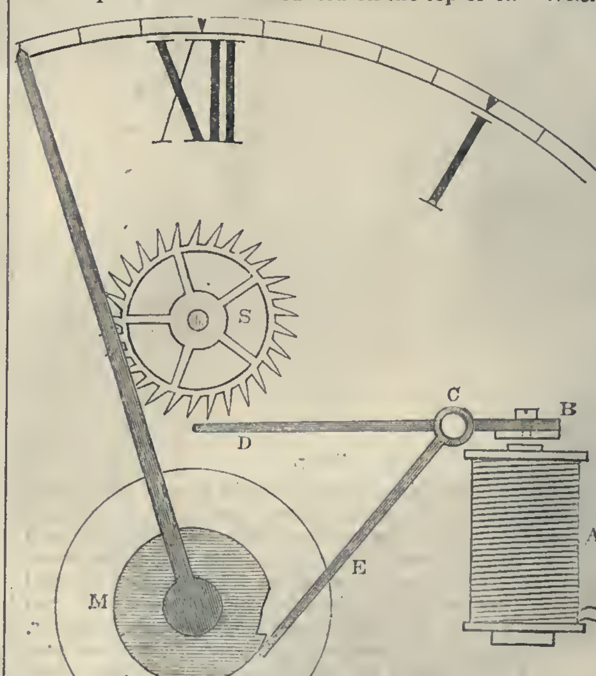

Fig. 12.

the clock, Fig. 11, reaches the hour, it allows the long

detent shown in the drawing to fall; this closes the circuit, and a hook attracted by the coil, catches a tooth cut in the escape-wheel, and holds it till the standard clock reaches the hour. At the hour the standard clock, Fig. 10, allows the lower detent to fall, and so breaks the circuit. Consequently the clock, Fig. 11, starts off side by side with the standard.

Mr. Ritchie, to whom we have referred before, has also devised a plan for correcting clocks by hourly currents. His clock, to be corrected in like manner, gains some second or two per hour. Fifteen seconds before each hour the lever D B (see Fig. 12) is attracted by the electro-magnet A, and a pin in the arm D would thereupon enter and catch a tooth of the escape-wheel, did the disc M allow the other arm of the lever E to move. When the hand reaches the hour, E falls, then D catches S and holds it till the cessation of the current at the sixtieth second of the governing clock.

Generally the use of a long telegraphic wire can only be commanded for a few minutes daily. Fig. 13 shows a very suitable arrangement to be adopted when this is the case. By means of the 24-hour disc the line wire is held in communication with the telegraph office until a

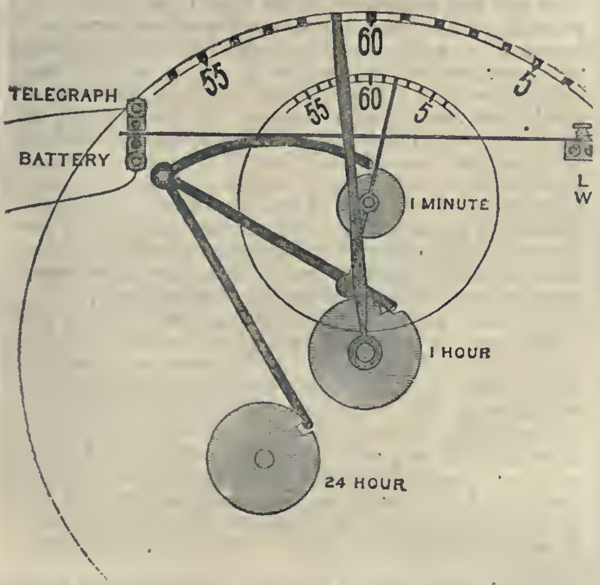

FIG. 13.

few minutes before the clock current is going to be despatched. The notch in the 24-hour disc will at last allow the system of levers to fall, but then the 1-hour disc supports them until about one minute before the clock current is coming; so that, till then, the line is being used for messages. The line wire has not been allowed to fall into circuit with the battery wire; this is still prevented by the 1-minute disc. At the sixtieth second precisely the 1-minute disc allows the line wire to join the battery wire, and out goes the clock current. Some seconds afterwards the 1-hour disc lifts the line wire back into communication with the telegraph office, where it stays for another twenty-four hours.

The Great Westminster Clock reports its own time to Greenwich by the following arrangement:—Some minutes before a signal is due, a lever is lifted by a slow wheel into such a position that a pin in the next wheel at its coming rotation will catch it. The second wheel lifts it so much further that a pin in the escape wheel reaches it, presses two slight springs together, and sends off the signal.

A method of driving an electric dial was contrived by the late E. J. Dent. A powerful magnet was lifted through a coil of insulated wire by a strong tower clock movement. Every half minute the magnet was dropped a current was generated in the coil, which proceeded to the dial and moved the hands. A plan on the same principle has lately been used for driving a number of small dials. A pendulum having a hollow coil of insulated wire for a bob, is by a heavy weight kept oscillating over a system of magnets. Currents are generated in the coil which proceed to the dials and work them.

Only the principal inventions in electrical clocks and clock-work have been indicated in this article. Since the year 1843 upwards of thirty patents have been applied for for improvements in such clocks and clockwork. It will be seen from this the subject, though not a wide one, is extensive.

Mr. Ritchie kindly lent diagrams 5, 6, 9, 12, and 13 to illustrate his plans, and M. Collin 10 and 11. Figs. 1 and 3 have been arranged to exhibit their working with clearness.

HENRY DENT GARDNER

TAUNTON COLLEGE SCHOOL

WE are sorry to chronicle the extinction of a school once watched with interest by all supporters of scientific education. The company which formed it is insolvent; the school buildings with the fine library and all the collections and apparatus which the late head-master amassed will be sold for the benefit of the creditors; the shareholders will lose their money; and the town will fall back for its higher education on the old, dilapidated, unhealthy grammar school.

The directors of the company, who constituted the council of the school, have performed no ordinary feat. Four years ago the school was nearly full, its annual profits considerable, its distinctions, and consequent reputation, unprecedented in so young an institution; public lectures in literature and science attracted to its hall large classes from the town and neighbourhood; and its systematic teaching of science to all its pupils was studied and imitated by many other schools. The council exhibited sudden activity; they starved the teaching-staff, interfered with the discipline and management, thwarted, harassed, humiliated the head-master. Warnings from parents and old pupils fell upon them unheeded. The last term of 1877 saw two open scholarships at Oxford, two places in Cooper's Hill, and a host of minor honours gained by the boys; but it saw also the head-master bullied into resignation, and all but a handful of the pupils withdrawn by their indignant friends. The fate of the school was clear to all except the council; it has lingered on only to add to the liabilities of the share-holders, who have now met to learn from their directors the history of a great scheme blighted, of insolvency far beyond the value of the mortgaged property, of their ancient school relapsed into the feeble, obsolete, provincial position from which Mr. Tuckwell rescued it.

ON SUPERSATURATION

A SOLUTION is a case of adhesion overcoming cohesion; and when these two forces are in equilibrium the solution is said to be *saturated*.

In general the adhesive force is diminished by lowering the temperature, and a portion of the solid, a salt, for example, is thrown down; but it is increased by raising the temperature, so that the liquid can take up an additional portion of the solid.

In the case of a large number of salts, but for the most part those that are hydrated, a solution saturated at a given high temperature can be reduced to a lower one without depositing any salt, in which case the solution is said to be *supersaturated*, because it contains more salt than it can take up at the reduced temperature.

For example, 100 parts of water at 194° F. will

take up 209 parts of potash alum, but at 32° only 4 parts. A boiling solution of alum containing 209 parts of the salt in 100 of water may be reduced, in a covered vessel, to the freezing-point of water without depositing any salt; in such case the water at 32° holds 52¼ times more salt in solution than it can take up at that reduced temperature.

The phenomena of supersaturation are, perhaps, best exhibited by means of Glauber's salt, or sodic sulphate, of which there are three forms, namely, the normal salt, containing ten atoms or proportionals of water of crystallisation, the seven-atom salt and the anhydrous. If two or three ounces of the normal salt in one ounce of water be gradually heated in a flask to 93° F., its point of maximum solubility, it will be completely dissolved, but if the heat be applied too suddenly or too fiercely, the anhydrous salt is thrown down, and occasions violent bumpings of the vessel. If the solution be properly conducted, it can be raised to the boiling-point, and so be left to cool (the mouth of the flask being covered) to the temperature of the air, without depositing any salt. It is now supersaturated. If, however, the solution be cooled to about 40° F. and under, the modified seven-watered salt is thrown down, the mother-liquor remaining supersaturated. If the flask be left uncovered, or the solution be touched with a proper nucleus, radiating lines, or rather plates of crystals of the normal salt, diverge from a point on the surface, and proceeding rapidly downwards, seem to interpenetrate the seven-watered salt, destroying its transparency, changing its molecular structure, whereby it assumes the appearance of boiled white of egg, and imparting to it three additional equivalents of water. The solution has now become solid, and the temperature considerably raised in consequence of change of state.

The condition of supersaturation was first noticed by Dr. Black towards the end of the last century, and from that time to the present many scientific men, both of this country and of the Continent of Europe, have studied the subject, often with contradictory results. The phenomena connected with the nuclear action of bodies in producing the sudden crystallisation of these solutions seem to behave differently in the hands of different inquirers; so that the facts affirmed by one writer are denied by another; and the theory which seems to have been disproved by one is again brought forward by another. Thus, to quote only a few of these contradictory statements, Ziz found that air and solids act best as nuclei when dry; if wet, or boiled with the solution or thrown into it while hot and allowed to cool with it, they are inactive: Löwel denies that air has any nuclear action, but that solids exposed to the air become active by a sort of catalytic force, and that alcohol is active: Liversidge and others deny that alcohol is active: Selmi states that dry air is nuclear, and acts by getting rid of water at the surface and producing crystals which continue the action: Gay-Lussac had before expressed a similar opinion: Lieben found that soot, platinum black, and pounded glass are nuclei: Schröder remarks that it is always a matter of chance whether such or such a substance produces crystallisation; Gernez, Viollette, Schiff, and Liversidge are satisfied that there is only one nucleus, and that is a salt of the same kind as the one in solution or isomeric therewith; and that when liquid and solid bodies apparently act as nuclei they are really contaminated with minute particles of the salt which is supposed to be always floating in the air: Jeannel opposes this theory, and Pellogio "gives proofs that the phenomena of supersaturation are not so simple as the French physicists would imply;" he finds that porous bodies act as nuclei: Viollette and Liversidge, on the contrary, find that porous bodies and bodies greedy of water and capable of being hydrated, such as absolute alcohol, fused sulphate of copper, quicklime, &c., are quite inactive.

In the midst of all this conflict of testimony, my own results were not likely to escape censure. Indeed, they have been attacked with a degree of acrimony which seems to be very much out of place in the calm inquiry after scientific truth, and in the presence of so many contradictory results produced by eminent conscientious observers. I was not able for a long time to account for the negative results which were opposed to my positive ones, and I threw the subject aside. At length, however, I was led to suspect that nuclei are powerfully affected by varying atmospheric conditions, whereby they sometimes determine the solidification of these solutions, and at other times not. Accordingly I undertook a series of daily observations which extended over some months, working with a standard solution of sodic sulphate and an essential oil, and the result was that when the wind at Highgate was northerly or easterly, the oil was nuclear, but with a westerly or southerly wind it was inactive. It was obvious, then, that there was some force present in the air which rendered the oil active, which being absent, the same oil remained passive. I succeeded in identifying this force with ozone, and judging that wherever ozone was present, irrespective of the direction of the wind, the oil would become nuclear, I visited several places, notably one by the sea-side, and was confirmed in the view I had taken. For example, at Eastbourne a westerly wind produced in the course of ten minutes a deep orange brown stain on ozone test-paper, and oils exposed to its action became singularly active after a few minutes' exposure. Freshly distilled oil of lemons, oil of cajuput, oil of turpentine, &c., were inactive in the house on supersaturated solutions of sodic sulphate and of alum, but by the sea-side far away from the town, with the wind blowing in the direction of the town, or at the end of the pier, 1,012 feet from the shore, with the wind blowing from the sea, the oils were allowed to fall in drops from a dropping tube into a small clean beaker for about three minutes, when they became powerfully active in rendering the solutions solid.

In my first papers on this subject (*Phil. Trans.*, 1868-1871) a nucleus is defined as a body that has a stronger attraction for the salt, or for the water of a solution, than subsists between the salt and the liquid. Examples are given in which oils, fixed and volatile, alcohol, ether, &c., spreading on the surface of the solution, produce a separation of salt, and the rapid solidification of the solution; whereas, if such liquids, instead of spreading, assume a lenticular form, they are inactive, and may, by shaking the flask, be dispersed through the solution in numerous globules without any immediate nuclear action.

Several circumstances favour the action of these liquids as nuclei: (1) Chemically clean flasks and solutions, so as to maintain (2) the surface tension of the solutions as high as possible, in order to spread a drop of oil, &c., into a film; (3) bright and clear weather, with strong evaporative force.

A newly distilled essential oil is inactive, on account of its strong cohesive force, and when a drop of it is dispersed in globules through the solution, each globule retains its surface-tension, whereby it is prevented from coming into contact with, and separating a molecule of the salt held in solution. The action of ozone is an oxidising one, diminishing the cohesive force among the particles of the oil, just as rust weakens the cohesive force of a bar of iron.

The effect which ozone produces quickly on a newly distilled volatile oil, is produced slowly on the same oil by long keeping. Its cohesive force is so far weakened, that a drop of it on the surface of the solution no longer tends to assume the lenticular form, or to disperse in globules through the solution. Then, as oil can adhere much more strongly to salt than to water, and the supersaturated solution being a highly charged system capable of yielding to a force that is exerted in the right direction, such an oil adheres to and separates a molecule of the salt, and the

action once begun is rapidly propagated, until the whole solution is solid.

In like manner newly refined fixed oils may have their cohesive force degraded by various chemical means, as by being treated with an alkali, or with nitric acid, &c., in which condition they are commonly nuclear. Solid and semi-solid fats, such as suet, dripping, lard, butter, fat of meat, &c., act powerfully as nuclei. The freshly cut surface acts most effectually, and, in some cases, a fat cut in one direction may not act for hours, while if cut in another direction it may act immediately. A glass rod smeared with lard, &c., may act better than a small lump of the material.

Several observers, who deny that the oils, &c., have any nuclear action, so contrived their experiments as to expose the oils, &c., to the action of heat, while carefully excluding the outer air. The effect of such manipulation is to increase the cohesive force of the bodies in question; and as they fail to act under such conditions, it was denied that they ever acted at all under other conditions, except when contaminated with particles of the salt more or less ultra-microscopic.

So also in testing the nuclear action of porous and dehydrating bodies, heat is employed, and this destroys the very activity which is about to be tested. Freshly ignited quicklime, for example, is inclosed in thin glass bulbs, sealed, heated to redness, and dropped into the supersaturated solutions. When cold, the bulb is broken, and the contents set free, but in no case with any result.

I have found that porous bodies, such as pumice, plaster of Paris, &c., may be rendered inactive by being treated for about ten minutes in a test tube plunged into boiling water. But when such bodies are thrown into the solutions without any separation of salt, it is not that exposure to heat has rendered them less active as nuclei; they have become in fact more active than before, for they now absorb the solution as a whole instead of its water only; whereas, if after being heated, these porous bodies are exposed to the outer air during ten minutes, they take in a little moisture which tames down their absorptive power, so that when placed in the solution they act more slowly, absorbing water and thereby producing a separation of salt and the solidification of the solution. Absolute alcohol acts in a similar manner. Crumb of bread is a very good porous nucleus.

As to the condition of sodic sulphate in solution there are many reasons for supposing that it is the anhydrous salt; that is, the normal salt gives up the whole of its water of crystallisation to the solution. When by a reduction of temperature a portion of the salt is separated, it combines with seven atoms of water, and this is not nuclear. So also when nuclei fail to effect the solidification of the solution, they cannot be said to be inactive, since they act within certain limits of temperature by throwing down the modified salt. But when nuclei are active in determining solidification they form a kind of *point d'appui*, which enables the disengaged molecule to combine with ten atoms of water, and this is nuclear to the rest of the solution and determines its solidification.

The state of supersaturation is dependent to a considerable extent on the adhesion of the solution to the walls of the vessel. If a portion of this be detached by rubbing or scratching the side below the surface with a strong clean wire the whole system breaks down and the solution immediately becomes solid. If the vessel, such as a test tube, be lined with resin, amber, or some substance to which the solution has a weaker adhesion, it generally becomes solid in cooling. Or if a highly supersaturated solution be poured boiling hot into a shallow vessel, in which the surface of adhesion and the free surface are nearly equal, the solution relieves itself by throwing down a considerable quantity of the modified salt, at temperatures above that at which it is usually formed in narrower and deeper vessels.

I have thus very briefly stated the results of my researches on this difficult subject, and submit them to the candid judgment of fellow-labourers in the same field.

C. TOMLINSON

OUR ASTRONOMICAL COLUMN

VENUS IN THE PLEIADES.—A thousand years ago and later the geocentric track of the planet Venus was occasionally such as to cause it to traverse the Pleiades, a phenomenon which, in these telescopic days, would be one of no small interest to the observer; prior to the invention of the telescope its effect would be merely to obliterate in a great measure, for the time being, the stars forming this group, particularly when the planet happened to be upon them near an epoch of greatest brilliancy. Amongst the observations collected from the Chinese annals and forwarded to Europe in the middle of the last century by the French Jesuit, Gaubil, we find one made under the dynasty *Tang*, in the fifth year of the period *Hwuy-Chang*, on the day *Jin-Woo*, of the second moon —corresponding in the Julian Calender to A.D. 845, March 16—when "Venus eclipsed the Pleiades;" the observation appears to have been made at *Si-gan-fou*, where the *Tang* dynasty had their court, and where the earliest occultation of a star or planet by the moon, that of Mars B.C. 69, February 14, was also observed. If we found an examination of this "eclipse" of the Pleiades by Venus, upon Leverrier's data, using them with a sufficient degree of approximation for the purpose in view, it appears that at dusk at *Si-gan-fou*, on March 16, 845, Venus was situate near the star *Electra*, not far from the parallel of the principal star of the group *Alcyone*, but three-quarters of a degree to the west of it, and that about the same time on the evening of March 17, after having passed close to *Maia*, the planet would be in the same right ascension as *Alcyone*, about twenty-four minutes to the north. Although the so-called eclipse of the Pleiades might commence therefore on March 16 as the Chinese record, Venus would be more centrally upon the group on March 17, according to our modern tables. Her apparent diameter was then thirty seconds, and she would shine with more than average brilliancy. Another eclipse of the Pleiades is mentioned under the later *Sung* dynasty, on March 10, A.D. 1002.

VARRO'S STORY OF THE ANOMALOUS TRACK AND FIGURE OF VENUS.—In a *résumé* of the recent progress of astronomy contributed to an American work by Prof. Holden, of Washington, we note a reference to a communication made by M. Boutigny to the Academy of Sciences at Paris in December, 1877, calling attention to a passage in Varro, which describes the planet Venus, as having about the year B.C. 1831 (not B.C. 31, as misprinted in Prof. Holden's Report) "changed its diameter, colour, figure, and course." M. Boutigny had probably overlooked the circumstance that this story of Varro's had been brought into notice long before, in a French work of astronomical authority, the "Cometographie" of Pingré, who, believing that the fable was originated by some celestial phenomenon, considered it was most probably due to the appearance of a bright comet. Pingré thus gives the fragment, preserved by St. Augustin:—"There was seen, says Varro, a surprising prodigy in the heavens, with regard to the brilliant star Venus, which Plautus and Homer call, each in his own language—the evening star. Castor affirms that this fine star changed its colour, size, figure, and track, which had never occurred before, and which has not occurred since. Adrastus, of Cyzicus, and Dion the Neapolitan, refer this great prodigy to the reign of Ogyges." Pingré's explanation will be found in "Cometographie," t. i. p. 247; the epoch he assigns for the phenomenon is "vers 1770."

The story has no astronomical importance, and is only noticed here from its revival so recently, as mentioned above.

NOTES

THE death is announced, at a venerable age, of Sir Thomas Maclear, F.R.S., formerly Astronomer-Royal at the Cape. We hope to be able to give a brief notice of his life and work in our next number.

AT a recent meeting of the Local Committee of the British Association Mr. Harold Thomas and Mr. W. K. Marples, the secretaries of the special committee for arranging the excursions, gave explanations concerning the proposed visits to twenty different places of interest in the district, including Chatsworth, Wentworth, Castleton, Cresswell Crags, Roche Abbey, Sandbeck, Welbeck, Thoresby, Matlock, Arbelow, Stanton-in-the-Peak, Conisborough, Haddon, Hardwick Hall, Bolsover, Wharncliffe, Stainborough, Beauchieff Abbey and Beauchieff Hall, Wingfield Manor, Bradfield, &c. At Arbelow, Sir John Lubbock is to give a lecture on the Druidical remains, which are a source of so much interest to antiquarians visiting that quarter. It was stated that Prof. E. Ray Lankester, F.R.S., had been appointed by the Association to take the place of the Rev. Mr. Dallinger, who is ill, as one of the lecturers for the meetings, and will deliver his lecture at the Albert Hall at 8.30 on Monday evening, August 25, his subject being "Degeneration." Among those who have already signified their intention of being present are Major Serpa Pinto, M. Daubrée, President of the Academy of Sciences, Paris; Prof. Zirkel, Professor of Geology, &c., Leipzig. There have also accepted the invitation to the Sheffield meeting the following, amongst others:—L'Abbé Renard, Keeper of Minerals of Royal Museum, Brussels; Prof. H. A. Newton, Yale College, N.H.; Dr. Wüllner and Madame Wüllner; Dr. Janssen, M. Veth, Leyden, Holland (a traveller in Sumatra); Lieut. Wyse, of the French Navy, and Madame Wyse.

IF any of our readers are within hail of Baden-Baden about the middle of September, they should not fail to pay it a visit some time between the 18th and 24th. The German "Naturforscher," we are sure, will give them a genuine welcome, and they will get a lesson worth learning of how an association of many hundreds from the cream of German science can as a united body combine the severest work with play so hearty as almost to approach "high jinks." In sections and out of sections the German *savants* meet as a body, work as a body, and enjoy themselves as a body. On the morning of September 18, for example, you can listen to Prof. Hermann, of Zurich, lecturing on the acquisitions of physiology in the last forty years, or to Prof. Hirschfeld, of Dresden, on mimic movements of the countenance from a Darwinian point of view, and in the afternoon listen to the military band at the foot of the old castle, finishing off at the theatre in the evening. On Saturday Dr. Nachtigal is to lecture, while the evening is to be devoted to dancing. Sunday is the great day for excursions, while Monday and Tuesday are devoted to sectional work, with fireworks, theatre, and concerts in the evenings. The session finishes on September 24, with, among other things, a lecture on food adulteration, by Dr. Skalweit, of Hanover.

THE biennial meeting of the International Astronomische Gesellschaft will take place at Berlin on September 5-8 next. Prof. Förster, director of the Royal Observatory, will, on application, give more detailed information.

IMMEDIATELY after the meeting of the German Association at Baden-Baden on September 14-24, the German Geological Society will hold its general meeting at the same place, viz., on September 25-28.

THE forty-seventh annual meeting of the British Medical Association was opened at Cork on Tuesday, Prof. O'Connor, of Queen's College, Cork, being president.

THE Cameron Prize, recently founded in Edinburgh University by the late Dr. A. R. Cameron, of New South Wales, "for the most important addition to Practical Therapeutics in the past year," has been awarded to Dr. Paul Bert, Professor in the Faculty of Sciences, Paris, for his researches extending over a series of years and summarised in his work entitled "La Pression Barométrique; Recherches de Physiologie Expérimentale" (Paris, 1878).

MR. TEGETMEIER, we understand, lends his aid as regards press-work of the reprints to be issued by the newly established Willughby Society, which could not have a more efficient director, as the fidelity of his reproduction of Moore's *Columbarium* and Boddaert's *Table* is enough to prove.

ON the morning of Sunday, August 3, a little before two o'clock A.M., the Royal Gardens at Kew were devastated by a hailstorm, which in the space of about ten minutes inflicted more damage than the Gardens have sustained since their existence as a national institution. After a rapid survey of the houses the following day, it was found that the number of broken squares of glass could not be estimated at less than 16,000. In the great temperate house alone 3,000 squares were shattered. The storm, which was accompanied by violent thunder and lightning, drove over the gardens from the north-east, and expended its greatest fury in the direction of Richmond. The temperate house suffered the full effects, while the palm house being apparently a little to the west of its course, escaped with the destruction of 700 panes. The hailstones were found to average one and a half inches in diameter, and to weigh three-quarters of an ounce. They came down with sufficient force to bury themselves in the bare earth of the flower borders, and even penetrate the turf to the depth of an inch. In some cases perfectly circular holes were cut out of the glass panes, while the hailstones went through the succulent leaves of the Echeverias planted out in the beds with as clean an outline as if it had been made with a punch. On account of the confusion produced by the damage and the danger from falling splinters of glass, it has been necessary to close all the houses to the public. The present low night-temperature, and the probability of heavy showers, are grounds for the gravest anxiety as to the preservation of the collections which, however speedy the repairs of the houses, cannot fail to suffer considerable injury. The damage is estimated at not less than 2,000*l*., as many of the houses being a good deal dilapidated, cannot be put in order without entire re-glazing, re-painting, and partial renewal, and application will have to be made to Parliament for a supplementary vote to defray the cost.

WHILE the Abbé Moigno will continue to edit *Les Mondes*, the proprietorship has been converted, he informs us, in the last number, into a sort of joint-stock company, thereby relieving him of all responsibility, and leaving him all his energy to carry on his scientifico-religious propaganda.

WE learn that the late member of the St. Petersburg Academy, Prof. Brandt, has left a mass of MSS. of great value. Among this are two important works which he has left unfinished; one on the contributions made by the St. Petersburg Academy for the advance of zoology, and a synopsis of the fauna of Russia. The MSS. will be published by the numerous friends the late Professor has left in the Academy, and by his son.

THE Royal Academy of Sciences at Munich has elected the following gentle men as Corresponding Members of its physico-mathematical class:—Prof. Edm. Hébert (Paris), Prof. J. F. Pfaff (Erlangen), Prof. Theod. von Oppolzer (Vienna), Prof.

Ant. de Bary (Strassburg), Dr. N. Pringsheim (Berlin), and Prof. O. E. Meyer (Breslau). Dr. Felix Klein of Munich has been elected as Extraordinary Member.

THE first congress of all the German societies for the protection of animals will be held at Gotha on August 17–19 next.

THE Imperial "Leopoldino-Carolinische" German Academy of Naturalists has presented the well-known Göttingen professor of physics, Dr. Wilh. Ed. Weber, formerly one of Gauss's collaborateurs, with the Cothenius medal, in recognition of his valuable services for the furtherance and progress of experimental physics.

THE following is the prize theme given by the physico-mathematical class of the Royal Academy of Sciences of Berlin:—According to Faraday's theory of electrodynamics, as worked out mathematically by Prof. Clerk Maxwell, the generation and disappearance of dielectric polarisation in isolating media as well as in celestial space, are phenomena which possess the electrodynamical effect of electric currents, and which can be called forth like the latter by electrodynamical induction forces. The currents in question would, according to the theory, be equal in intensity to that one which charges the boundary surfaces of the conductors electrically. The Academy now demands that decisive experimental proofs be given for or against the existence of electrodynamical effects of nascent or disappearing di-electric polarisation, of the intensity supposed by Prof. Maxwell, or for or against the generating of di-electric polarisation in isolating media by means of electromotoric forces induced magnetically or electrodynamically. The term for sending in solutions of the theme ends on March 1, 1882.

ON the 1st inst. a century had passed since the birth of the celebrated naturalist and philosopher, Lorenz Oken (properly Ockenfuss). Oken was born on August 1, 1779, at Bohlsbach, in Swabia, and died on August 11, 1851, at Zurich. He had held for many years the post of professor of natural history at Jena, Munich, and Zurich. His principal works are the well-known "Lehrbuch der Naturgeschichte" and "Allgemeine Naturgeschichte für alle Stände."

RUSSIAN newspapers announce, as we stated last week, that a very rich archæological find has been made by M. Kibalchich, in Southern Russia, on the banks of the Trubesh River, in the Government of Poltava. In a locality covered with numerous small mounds, a sheet of earth with pieces of coal, bones, broken pieces of earthenware, as well as stone and bronze implements, were discovered under the recent sands. The number of stone arrows and knives discovered is no less than 372; besides, M. Kibalchich has found two larger stone implements which were used for breaking great bones, several clay and glass ornaments, earthenware with ornaments, and five bronze arrows. This find is the first in Southern Russia, whilst, as is known, the remains of the stone and bronze periods are very numerous in Northern and Eastern Russia.

A CAPTIVE balloon has been established in Berlin, and was inaugurated on July 27. But the wind having blown with some velocity, the balloon was opened, and the occupants of the car were precipitated to the ground. A tree having diminished the shock, the travellers escaped almost unhurt. The Berlin balloon was about $\frac{1}{11}$ the size of the Paris balloon, inflated with coal gas, and the cover ordinary silk. The *Norddeutsche Zeitung* asks for police inspection before new ascents be made. The intended height was only 500 feet, and the number of passengers two or three.

ON August 30 M. Gaston Tissandier made an ascent from La Villette Gas Works with his wife and his brother. The travellers started at 5h. and landed at 7h. 50 at Dawmartin. The observations were highly interesting. When the *National* left ground, the wind was blowing south-westerly, but at about 7h. the direction changed abruptly, and an instantaneous change took place in the direction of the balloon. It was caused by the *brise de mer* setting in after a hot day. The sky was covered with cumulus, intermixed with a few cirrus of small dimensions. When at an altitude of 600 metres, M. Tissandier passed through a cloud which was very cold indeed, as proved by the sensation which the travellers experienced, but the duration of the passage was so short that it was not possible to observe the temperature at the thermometer. When at a higher altitude M. Tissandier observed the refraction of the rays of the sun on icy particles, and at the same moment on the western sky splendid rainbows. At the same time a very large halo had been observed at Paris by the *Temps* meteorological editor, and noted by him.

DR. DUNANT publishes in the *Journal de Genève* a note on the low temperature of this summer. While the mean temperature for the years 1873 to 1878 was 18°·9 Celsius in June, and 21°·0 during the first half of July, in 1879 it was only 18°·8 and 16°·7.

THE Ramon Société of Toulouse is organising an ascent on the Pic du Midi, to inspect General Nansouty's Observatory. The peak is covered with unseasonable snow, but it will not prevent the ascent from taking place, it is expected, without any great difficulty.

A SHOCK of earthquake was felt on July 20 at 3·30 A.M. at Vulpera, in the Engadine (Switzerland). It was accompanied by a rather strong rumbling.

AN earthquake consisting of three moderately violent shocks is reported from Cairo. The phenomenon was observed in the night of July 11-12. In the quarter of Bab-en-Nasr, which is at some distance from the modern portion of the city, some isolated walls fell in, and an old and somewhat dilapidated minaret has suffered so severely that it must be taken down. During the last decades earthquakes have been extremely rare at Cairo and indeed in Egypt generally, and since the great earthquake of 1857, which caused so much damage amongst the shaky old buildings, in which the Caliph-city abounds, and through which several lives were lost, no earthquake of importance has occurred. The phenomenon of July 11-12 is said to have been noticed also at Gizeh, near the great pyramids.

THE Manila papers state that a terrible thunderstorm passed over that city on May 31. It was preceded by an almost suffocating warm atmosphere and rain, and lasted about an hour. The lightning struck the Binondo Tower, damaging the crystal shade of the clock, but not injuring the mechanism, though the stone work forming the arch was much damaged. Out of several persons in the tower at the time, four appear to have been killed. Several other places in the city were more or less injured.

WE have received from Mr. Henry Chichester Hart, B.A., a copy of his collected papers "On the Flora of North-West Donegal," which have been appearing in the *Journal of Botany*. These floras of particular districts are valuable contributions to a perfect knowledge of the British flora in general, for it is evident that a more thorough exploration of a given range can be better effected by confining the observation to a small circuit than by extending them almost indefinitely. Many points of interest in the localities of species are more clearly indicated by these contributions than we expect to find in a work which treats of the flora of the entire country. As an illustration of the utility of these papers we may refer to the fact that *Ophioglossum lusitanicum*, L., was found by Mr. Hart in August last amongst short grass near the margin of a cliff on the northern side of

Horn Head; the fronds were fertile at the time notwithstanding that the plant has been usually quoted as flowering in January. Mr. Hart further points out that the claims of this fern to a place in the British flora have hitherto rested upon its known habitat in Guernsey.

In the June number of *The California Horticulturist*, amongst other articles of horticultural and local interest, is one on the Sierra Forests, pointing out the great risk there is of these magnificent forests becoming denuded as they "are now and for many years have been, at the mercy of private greed and public theft." The writer says it is true no changes are yet manifest, there are miles of forest left, and ravines wherein no chopper's axe has yet resounded. It is not the axe that is feared but the sheep and cattle owned by private individuals that have for years been pastured on the Government lands of the Sierras. The common practice, it is said, has been for a man having perhaps five or ten thousand head of sheep to purchase one single quarter section from the Government to build his house on, and perhaps to hold the best springs of water. From that central point his flocks and herds roam for miles, under the spicy pines and cedars, trampling the soft rich ground until it is like iron, destroying every seed, killing all the young trees, and causing the State a yearly loss in the value of her forests, which is far more than the worth of the whole band of sheep. The article concludes with a reference to the matter having occupied the attention of some of "our best thinkers." "Prof. Sargent, of Harvard," we are told, "points out in the *Nation* the disastrous effects of such a policy; Prof. Hooker, of Kew Gardens, follows in the same line of thought; and John Muir mourns over the desiccated forest-shrines, and the rarer flowers and ferns, now rapidly passing out of existence."

Messrs. Longmans and Co. have just issued a little book on "Town and Window Gardening," being the substance of a course of lectures "given out of school hours to pupil teachers and children attending the Leeds Board Schools." These lectures were given by Mrs. C. M. Buckton, a member of the Leeds School Board, and author of two recently published books called respectively "Health in the House," and "Food and Home Cookery." These endeavours of Mrs. Buckton to raise the moral and intellectual welfare of the working classes are highly praiseworthy, and though the book before us may not claim a position amongst standard scientific works, yet there is much that is good scattered through it which cannot fail to raise the tastes of many a child fortunate enough to come under the influence of teachers like the authoress who have a real admiration for nature in all its branches and a heartfelt desire to impart as much knowledge as possible to the children of our crowded alleys.

The Tasmanian gold-fields are reported to be very successful, and some rich finds have occurred on the Pieman River. The locality is about seventy miles across country from the tin deposits at Mount Bischoff. Numbers of people are flocking to the diggings from all quarters.

The additions to the Zoological Society's Gardens during the past week include a Weeper Capuchin (*Cebus capucinus*) from Guiana, presented by Capt. Bond; a Brown Bear (*Ursus arctos*) from Russia, presented by Mr. J. R. Boyce; a Tawny Eagle (*Aquila nævioïdes*) from Southern Spain, presented by the Marquis de la Granja; a Bateleur Eagle (*Helotarsus ecaudatus*) from the Isle de Bas, Sierra Leone, presented by Mr. Alex. Sinclair; two common Crossbills (*Loxia curvirostris*) European, presented by Mr. H. A. Macpherson; a Common Cuckoo (*Cuculus canorus*), British, presented by Miss C. Bealey; a Central American Agouti (*Dasyprocta isthmica*) from Central America; two White-faced Tree Ducks (*Dendrocygna viduata*), a Red-billed Tree Duck (*Dendrocygna autumnalis*) from Rio Magdalena, purchased.

SOUTH CAROLINA FOSSILS

In a paper on "Vertebrate Remains, chiefly from the Phosphate Beds of South Carolina," published in the *Journal* of the Academy of Natural Sciences of Philadelphia (vol. viii. part iii.), Prof. Joseph Leidy prefaces his careful description of the many separate remains by a few general remarks on the subject, some extracts from which may interest our readers. The fossils are mainly from the so-called Ashley phosphate beds of South Carolina, which "are composed of sands and clays, intermingled with irregular porous masses of more coherent rock rich in calcium phosphate, together with many organic remains. These beds, the economical importance of which was fully made known in 1868 by Prof. Francis S. Holmes and Dr. N. A. Pratt, of Charleston, occupy a large extent of country in the southern part of South Carolina, on the Wando, Cooper, Ashley, Stono, Edisto, Coosaw, Asheepo, and other rivers. According to Prof. Holmes, from 'fifteen to eighteen inches may be considered the average thickness of the stratum of the phosphate rocks.'[1]

"The exact stratigraphical relations of the beds and the relative age of these and contiguous strata have not been as thoroughly investigated as is desirable, and in many cases the particular horizon to which belong the fossils that have been discovered has not been positively determined. According to Prof. Holmes, the phosphate beds are of the post-pliocene period and overlie strata pertaining to the pliocene period and these are again succeeded by a soft marl rock of eocene age, the whole being covered by modern alluvium.

"The phosphatic rocks or nodular masses of the phosphate beds, said to contain as high as sixty, or even more, per centum of calcium phosphate, are of irregular shape, and range in size from small pieces up to masses of a thousand pounds or more.[2] They contain many casks of molluscous shells, which appear to be of the same forms as those which occur in the eocene or miocene marl rock beneath. They also frequently contain imbedded bones and teeth, mainly those of marine fishes and cetaceans.

"The phosphatic nodules are supposed to have been derived from the tertiary marl bed beneath, and are considered to be detached and altered fragments from the surface of that bed. The irregular, eroded, and porous masses have the appearance of being detached and water-rolled fragments of the tertiary marl rock after it had been tunnelled by various boring molluscs. It is, indeed, not improbable, as has been suggested, that in the later part of the eocene or miocene period and subsequently the easily penetrated rock was bored and rendered spongy by the incessant labours of multitudes of *Gastrochæna*, *Petricola*, *Pholas*, &c. At the time or later, neighbouring and superficial islets, the resorts of myriads of sea-fowl, may have furnished the material which, when washed with the ocean and mingled together with the decomposing remains of marine animals, supplied the element for the conversion of the porous marl rock into the more valuable phosphatic compound.

"Besides the phosphatic nodules, the Ashley beds present a remarkable intermixture of the remains of marine and terrestrial animals, consisting of bones, teeth, coprolites, shells, &c., derived from the contiguous formations of various ages from the early tertiary to those of a comparatively recent period.

"Of remains of vertebrates, those of fishes and cetaceans prevail, especially the teeth of sharks and the vertebræ of whales. Less frequently there occur the vertebræ and teeth of large teleost fishes, the dental pavements of rays, fragments of turtle shells, vertebræ of crocodiles, ear-bones and teeth of cetaceans, bones of manatees, &c. With these likewise are found the remains of both extinct and still existing terrestrial mammals, especially teeth and bone fragments of elephant and mastodon, megatherium, horse, tapir, bison, and deer. More rarely there are found remains of hipparion, castoroides, hydrochærus, and of the smaller and more common genera of species.

"The fossils mainly consist of the harder parts of the skeleton and of teeth, usually more or less water-worn, indicating shallow seas and an active surf to which they were exposed. Many of them exhibit the drilling effects of boring molluscs, especially those which are supposed to have been derived from the tertiary marl rock, the operation of drilling apparently having been performed both before and during the time the fossils were embedded in the rock. Only enamel or the enamel-like dentinal

[1] "The Phosphate Rocks of South Carolina." By Francis S. Holmes, A.M., Charleston, 1870, p. 70.

[2] A nodular mass, on exhibition in the government building, from Charleston, S. C., weighs 1,150 pounds.

layer such as is found investing the crown of the teeth of sharks, appears to have been a protection against the drilling power of the borers.

"Fossils excavated from the phosphate beds are of a ferruginous brown colour, but often much lighter or white upon the surface. Those which are obtained from the rivers contiguous to the beds are usually more or less black, with the enamel of teeth iron-gray, and they frequently exhibit the basal attachment of small barnacles, and occasionally the valve of an oyster.

"From the fossils consisting mainly of the harder and denser, and therefore heavier parts of skeletons and teeth, they are generally assumed to be petrified, but usually the change has not been more than a moderate loss of the ostein basis and the infiltration of iron oxyd.

"From the extraordinary variety and profusion of the fossil remains of the Ashley phosphate beds it may be inferred that these were the former rich feeding grounds for multitudes of marine and amphibious animals. At an early period during the formation of the tertiary marl here congregated great sharks, rays, squalodons, &c. At a later period their successors varied their diet with the carcases of great land animals, as elephants, mastodons, &c., which floated down the broad and swollen rivers, as drowned herds of the bison are said to do in our day upon the Missouri River.

"Some of the remains of terrestrial animals, comparatively few in number, found as fossils in the Ashley phosphate beds, including even the softer or more spongey bones, exhibit no evidence of violent water action other than the signs of decay from the combined influence of moisture and air; neither do such fossils exhibit the marks of boring molluscs, nor the attachments of barnacles. Usually black and more or less friable, these fossils, such as the bones of mastodon, megatherium, deer, &c., are no doubt the remains of animals which became mired and sank into marshes of the Ashley phosphate beds after these had become elevated above the surface of the neighbouring sea. Of this nature, also, we may believe, are the remains of more recent animals, including also specimens of human bones, those of domestic animals, and stone implements, which are occasionally found in the Ashley phosphate beds."

SCIENTIFIC SERIALS

American Journal of Science and Arts, July.—Contributions to meteorology, by E. Loomis (eleventh paper).—Silurian formation in Central Virginia, by J. L. Campbell.—New form of spectrometer, and on the distribution of the intensity of light in the spectrum, by J. W. Draper.—Extinct volcanoes about Lake Mono, and their relation to the glacial drift, by J. Leconte. Mineral locality in Fairfield Co., Connecticut, by G. J. Brush and E. L. Gazetta Chimica Italiana., fasc. iv. and v.—On nicotine, by S. Andreoni.

SOCIETIES AND ACADEMIES

Geneva

Society of Physics and Natural History, February 6.—M. L. Lossier explained a special method which he has introduced for assays of gold.—M. Albert Rilliet gave an account of a research made by him and M. E. Ador on the hydrocarbons obtained by the action of the chloride of methyl on benzine in presence of chloride of aluminium.

February 20.—M. H. de Saussure described an apterous insect of Gaboon, whose mode of life is unknown, and which has been described under the name of *Hemimerus*. It has the remarkable characteristic of possessing a second lower lip provided with palpi, and several other characteristics make it an insect of an altogether special nature, difficult to classify in any of the known orders.

March 6.—M. Casimir de Candolle has studied the anatomy of the leaves of some cotyledons, and particularly the internal conformation of their petiole, or the principal nervure. This petiole shows in its centre a woody bundle presenting very varied forms—sometimes that of an arc, sometimes that of a complete ring. Besides this complete ring, there are frequently observed woody bundles placed outside the ring, and which M. de Candolle calls cortical; at other times bundles inside the ring, and which M. de Candolle calls intra-medullary.—M. Ph. Plantamour observed during the cyclone of February 20 a notable depression of level of the Lake of Geneva. The wind produced this effect of depression notwithstanding the diminution of atmospheric pressure indicated by the barometer, and which would tend to raise the level of the water. When the wind assumes the form of a whirlwind, it produces an aspiration instead of a depression. The rate of the cyclone referred to appears to have reached at least 24 metres per second.

March 20.—Prof. E. Plantamour presented a quarto volume entitled "Telegraphic delimitation of the difference of longitude between Geneva and Strasburg," published by himself and M. M. Löw. This operation, executed in 1876, resulted in a difference of 6m. 27·934s.—M. D. Colladon, on the occasion of very remarkable cases of *verglas* observed in Paris on January 20 and 23, recalled former cases described by him and others (see *Comptes Rendus*, t. lxxx. viii., March 31, 1879).

April 3.—M. Raoul Pictet communicated the continuation of his researches on the theory of heat. He admits that the amplitude of the oscillations of molecules around their position of equilibrium may be taken as a measure of heat, or as corresponding to the temperature. He explains by this definition the properties of fusibility of metals and the anomalies of Mariotte's law.—Prof. Brun described a curious case of poisoning in a child of two years, resulting from eating a combination of cabbage and figs. The cabbage must have produced a great abundance of lactic acid, which in presence of the glucose of the figs had produced buteric acid in sufficient abundance to cause the death of the child.

April 17.—Prof. Alph. Favre has found iron in the state of particles attractable by the magnet in all the earths and rocks of the country around Geneva which he has examined. This iron, in grains, not being soluble, cannot be considered in the analysis of arable soils, as profitable to vegetation. Hence erroneous conclusions resulting from these analyses, which suppose more iron than there is possible for vegetation. The origin of this iron is attributed in part to the *débris* of meteorites.

Paris

Academy of Sciences, July 28.—M. Daubrée in the chair.—The following papers were read:—Researches on the refraction of obscure heat (continuation), by M. Desains.—Note on the hydrate of chloral, by M. Wurtz.—Observations on the memoir of MM. Noble and Abel on explosive substances, by M. Berthelot.—On the theory of hail, according to MM. Oltramare and Colladon, by M. Faye. M. Boussingault also made some observations on the subject.—On the effect of electrical excitations applied to the muscular tissue of the heart, by M. Marey.—Memoir on the temperature of the air at the surface of the ground and of the earth to 36 m. depth, as also on the temperature of two soils, one exposed, the other covered with grass, during the year 1878, by MM. Ed. and H. Becquerel.—Researches on samarium, radicle of a new earth extracted from samarskite, by M. Lecoq de Boisbaudran.—MM. Georges Pouchet and S. Jourdain were then nominated candidates for the chair of Comparative Anatomy at the Natural History Museum, vacant through the death of M. Paul Gervais.—M. Daubrée then reported on the experimental researches of M. Stanislas Meunier, relating to the meteoric nickel-iron and native carburetted iron of Greenland.—Two memoirs were presented to the Academy, one by M. David, on the development of algebraic functions, the other by M. Poincaré, on the effect produced by the inhalation of nitrobenzole vapour.—On some observations of planets (198) and (200), made at the Marseilles Observatory, by M. Stephan.—On an application of rational mechanics to the theory of equations, by M. F. Lucas.—On the action of light on electric piles, by M. H. Pellat.—On the refrigerating action of air at high pressure, by M. A. Witz.—On the distillation of a heterogeneous liquid, by L. Troost.—On the quantities of organic matter in mineral waters, by G. Lechartier.—Thermo-chemical researches on the soluble alcaline sulphides, by M. Sabatier.—On the decomposition of sulphide of ammonium, by MM. R. Engel and A. Moitessier.—On the calcination of turnip-molasses, by M. C. Vincent.—On the influence of sugar injected into veins upon the secretion of urine, by MM. Ch. Richet and R. Moutard-Martin.—On the irritability of a muscle during the different periods of its contraction, by M. Richet.—On the discovery of medicaments and poisons in saliva, by M. Gabriel Pouchet.—Comparison of the influence of intravenous injections of chloral, chloroform, and ether, by M. Arloing.—On the lympho-glandular organs and the pancreas of vertebrates, by M. Renaut.—On some multinuclear animal and vegetable proto-organisms, by E. Maupas.—On the two great phases of the annual circulation of the atmosphere, by L. Brauet.—Experiments on milk-production, by M. Lami.—On the formations of the so-called "Dombes," by M. Nivet.—On the palm-wine of Laghouat, by M. Balland.

THE DISSOCIATION OF CHLORINE

DURING the past few years the well-known chemist, Prof. V. Meyer of Zurich, has rendered signal service to his brother workers by the introduction of numerous improvements in methods of determining vapour densities. At about the close of last year, in conjunction with Herr C. Meyer, he described a simpler method than any hitherto introduced, available for high temperatures, and yielding results of very considerable accuracy.

This method consisted in heating a vessel to a temperature at which the substance whose vapour density was to be determined was completely converted into gas, then introducing a small weighed quantity of the substance in question, and subsequently measuring, at the ordinary atmospheric temperature and pressure, the air displaced from the vessel by the vapour of the substance. In this manner, the volume of vapour, measured at the atmospheric temperature and pressure, generated by a known weight of substance is ascertained, and the density deduced from these data by a simple calculation. The great advantage of the method is that it does not require a knowledge of the temperature of the vapour, and the entire series of operations may be performed in a very short space of time.

The apparatus employed is also extremely simple, and consists of a cylindrical bulb of about 100 c.c. capacity, sealed to which is a glass tube about 6 mm. in diameter and 600 mm. long; this tube is widened out at the open end, so as to admit of the introduction of a caoutchouc stopper, and has a side tube, 1 mm. in diameter and 140 mm. long, sealed on to it about 100 mm. below the open end. The side tube is once bent nearly at right angles and the end slightly turned up, so that, when dipped into water, it will deliver gas into a graduated glass vessel inverted over it. For determinations at high temperatures the bulb is constructed of porcelain and is heated in a gas furnace; when operating at lower temperatures the bulb is heated either by means of a vapour bath or in a bath of molten lead. The operation consists in heating the bulb until it acquires a constant temperature, which is indicated by the non-appearance of air-bubbles at the orifice of the side tube which is plunged under water; the stopper is then removed, the weighed quantity of substance introduced and allowed to fall into the bulb, the stopper quickly reinserted, and the end of the side tube then brought under the measuring vessel; directly air ceases to issue from the extremity of the tube, the stopper is removed, and the air thus collected is afterwards measured in the usual manner. In the case of substances which undergo oxidation when heated in air, the air is first displaced from the apparatus by a current of pure nitrogen.

Operating in this manner, the Messrs. Meyer have determined the vapour density of a variety of inorganic compounds, such as indium chloride, stannous chloride, cuprous chloride, zinc chloride, ferric chloride, phosphorus pentasulphide, and arsenious anhydride, and have obtained results showing the molecular formulæ of these substances to be as follows:—

$$InCl_3,\ Sn_2Cl_4,\ Cu_2Cl_2,\ ZnCl_2,\ Fe_2Cl_6,\ P_2S_5,\ As_4O_6.$$

They then directed their attention to elementary bodies, and in a recent communication to the Berlin Chemical Society, they describe the results of experiments, showing that at a temperature as high as about 1,567° C. the molecular composition of mercury, oxygen, nitrogen, and sulphur is correctly represented by the formulæ—

$$Hg,\ O_2,\ N_2,\ S_2,$$

which are those generally adopted.

But with chlorine they obtained very different results. They employed platinous chloride as the source of this body, as it can be obtained perfectly dry and readily splits up into chlorine and platinum when moderately heated; a known weight of the chloride was introduced into the bulb in each experiment, the air having been previously expelled by a current of nitrogen. The numbers obtained in a first experiment at about 620° C. agreed with those required on the assumption that the chlorine molecule has the formula Cl_2, which is that generally accepted; but on determining the density at about 800° C. a lower number was obtained, and a still lower density resulted from experiments at about 1,028° C. and 1,242° C., but no further change of density was observed on making determinations at temperatures of about 1,392° C. and 1,567° C. The density (referred to air) observed at the various temperatures was as follows:—

Approximate temp.	Density.	
620°	2·42	2·46
808°	2·21	2·19
1028°	1·85	1·89
1242°	1·65	1·66
1392°	1·66	1·67
1567°	1·60	1·62

The density at about 1,200° and above, it will be observed, is two-thirds of the density at 600°; the change in volume undergone by chlorine when heated is therefore precisely similar to that undergone by oxygen in its passage from the condition of ozone to its ordinary condition, and it might therefore be supposed that a similar change had taken place. The researches of Sir B. Brodie have placed it beyond doubt that if we regard ordinary oxygen as having a diatomic molecule represented by the formula O_2, ozone has a triatomic molecule of the formula O_3, the conversion from ozone into oxygen being represented by the equation—

$$2O_3 = 3O_2.$$

Inasmuch, however, as chlorine has the atomic weight 35·4, such an explanation of the change in density of this gas is inadmissible; it would only be possible if what we at present regard as the atom of chlorine is a compound of 3 sub-atoms each of the weight $\frac{35 \cdot 4}{3}$. The only other explanation, however, which can be given is that chlorine after all is not an element but a compound of at least two elements which are dissociated by heat. Mr. Watson Smith in a letter from Zurich, printed in the *Chemical News* of last week, states that the Messrs. Meyer incline to this latter explanation, and that in all probability *oxygen is one of the components of chlorine*; we hear also from another source that they have actually separated oxygen from it, but hitherto no description of this part of the investigation has reached us.

It needs not to be pointed out that such a discovery as is here foreshadowed is of the highest importance. There can hardly be a doubt that if chlorine be found to give way

R

so easily, other so-called elements, and especially those which, like bromine and iodine, are closely related to chlorine, will not long resist the attacks to which they will now be subjected; indeed, the Messrs. Mayer already state in their paper that the behaviour of iodine is similar to that of chlorine.

In concluding this notice I cannot refrain from stating that to my knowledge Mr. Lockyer has for several months past been engaged in the spectroscopic investigation of the non-metals, and that he has repeatedly assured me that the views he has already published with regard to the metals are equally applicable to the non-metals. He has shown me, moreover, that with the spark at a particular tension the *red line of oxygen* is one of the most prominent lines in the spectrum of chlorine, the freedom from which of admixed air and moisture is attested by the absence of the characteristic nitrogen and hydrogen lines. Mr. Lockyer regards this as confirmatory of the Meyers' discovery.

HENRY E. ARMSTRONG

SCIENCE IN THE ARGENTINE REPUBLIC

Description physique de la République Argentine; d'après des Observations personelles et étrangères. Par le Dr. H. Burmeister, Directeur du Museo Público de Buénos-Ayres. Tome Cinquième: Lépidoptères, 1re Partie, contenant les Diurnes, Crépusculaires et Bombycoides. (Buénos-Ayres, Paris, et Halle, 1878, 8vo.; Atlas de xxiv.[1] Planches, 1879, 4to.)

IN commencing a notice of this work it is impossible to avoid an expression of admiration for the persistent energy displayed by its septuagenarian author. Half a century has elapsed since his "inaugural dissertation" (on an entomological subject) was read at Halle, and during this time a continuous flow of valuable works and articles has appeared from his pen, not only in the long period of his professorship at Halle but also since he became permanently located in Buenos Ayres. Now, at an age when most men who have attained it have lapsed into "the sere and yellow leaf," so far as laborious work is concerned, we find him undertaking a gigantic enterprise, of which entomology is only a portion. All those who have had occasion to consult his former works will heartily acquiesce in the hope that he may live to complete this.

Without doubt the most valuable features of the volume under consideration consist in the numerous direct observations by the author and his son, on the structure and life-histories of the insects treated upon, from living subjects, in contradistinction to what may be termed mere museum work. In one respect disappointment will be felt. It might have been expected that an author of such vast experience, and with such admirable opportunities, would have been explicit in expression of opinion on those important subjects of philosophical inquiry that now occupy the attention of all entomologists, and for which South America furnishes such notable materials.

On the question of mimicry he appears to be absolutely silent, contenting himself by occasional remarks on the fact of resemblances, but without comment. On the theory of evolution he is scarcely more explicit, and the only remarks that bear, even indirectly, on this subject are those that appear in the "Avertissement" to the description of the plates, where he says:—

"I am unable to share the views of those specialists who augment the number of species indefinitely by slight variations; on the contrary, I am a partisan of the opinion, well founded on experience, that each species, although from a scientific point of view fixed and up to a certain point invariable, is forced to modify itself under different external influences of climate and food, and that these influences may, to a certain extent, alter some of the subordinate specific qualities. This faculty will be greater in proportion as the territory over which the species is spread may be more vast, and one will only find altogether invariable, those local species that have never quitted their place of origin. From this restricted point of view I am a partisan of the theory of the variability of species."

From this it will naturally be understood that our author is no advocate for the reckless creation of "species" now so alarmingly put in practice, to apparently little other purpose than the gratification of the vanity of those species-makers who wish to see their names attached to an endless list of synonyms. That the author is right in his reductions in the case of those species inhabiting the region immediately under his observation, possibly few only will dispute, and, above all, not those who know the exactitude of his critical powers in this respect; but other reductions concerning forms from the more northern parts of the South American Continent may be open to question, unless on the standpoint taken as to the value of the term "species."

The existence in the southern portion of the vast continent of South America of certain genera belonging to the nearctic fauna, has not escaped the author's notice. He alludes to the subject more than once, even in connection with the purely Argentine fauna, but without further comment.

The introductory anatomical portion is, as might have been expected, of the utmost value, and may be studied with advantage by students of Lepidoptera generally. Exception might probably be taken to too great importance being attached to the covering of scales as an attribute of the order. Instances (p. 1) might have been cited of the existence of "scales" in other orders, such as the well-known *Podura* and *Thysanura*, many *Curculionidæ*, some *Trichoptera*, certain forms of *Psocidæ*, &c., if not on the trunk itself, at any rate on the wings and other appendages.[1] An entire chapter is devoted to the structure of the scales, and the conclusion arrived at is that the well-known longitudinal striations exist only on the *upper* surface; if the writer mistake not, microscopists have arrived at the same conclusion from an examination of that favourite "test-object," the "*Podura*-scale."

As in all his works, the author shows himself a rigid advocate for "purity of nomenclature," and does not hesitate to adopt the spelling he considers the more correct. On the question of priority we read (p. 110): "The strict observance of priority of nomenclature appears to me an exaggeration of scientific law; I prefer names given by masters, such as Linné, Fabricius, Latreille, &c., to those of simply collectors, as Cramer, Drury Donovan, &c., following the axiom *au mérite la couronne*." Regarding these words from a sentimental point of view,

[1] Of these only sixteen have as yet appeared.

[1] The neuropterous genus, *Coniopteryx*, cited by the author (p. 1, footnote), has no scales; the covering is apparently a waxy secretion, soluble in ether.

few will object; but the possibility of applying them in the present state of science is, and probably will be, fiercely contested; and it may be justly urged that the descriptions in the works of the masters he alludes to, would not, in many cases, have been recognisable had the types not been in existence, or had it not been for the beautiful iconographic works of those authors whom he somewhat derogatively terms "simply collectors."

Turning to the purely systematic arrangement of the author, we find the *Lepidoptera* divided into *Rhopalocera* and *Heterocera*, or into *Diurna*, *Crepuscularia*, *Nocturna*, and *Microlepidoptera*. This is broad grouping, and we shall be curious to see, in a future volume, how it is proposed to get over the difficulties of the last-named. On some points of minor arrangement the author's views will be regarded as rank heresy by most entomologists of the present day; and the most notable of these are the positions assigned to those anomalous groups known as the *Castniadæ* and *Uraniadæ*, which are boldly united with the *Rhopalocera*, as groups 10 and 11 of that division, in opposition to the ideas of almost every one, and notably to those of Boisduval and Westwood (the latter author's recent memoir on the genus *Castnia*, and others, in the *Trans.* Linn. Soc., ser. 2, Zoology, vol. i., 1877, is alluded to in the text attached to the plates). It is scarcely to be expected that the reasons given for this course will be found convincing to the majority; could it be so, the arrangement would be hailed with satisfaction by those numerous collectors who, confining themselves to "butterflies" only, are now debarred from adding to their stores some of the most beautiful insects that exist. The *Crepuscularia* are divided into *Sphingidæ* and *Sesiadæ*; the *Zygænidæ* are not represented in the author's faunistic region, but the *Glaucopidæ*, often associated with them, are transferred to the *Bombycoides*, and head that section. Many other points might be alluded to in which the author departs from common practice in systematic views, but it is only fair to him to state that, in all cases, he gives the fullest reasons for adopting the course, however insufficient they may appear to others; but this notice has already become too lengthy, and they must be left to the discretion of specialists, all of whom must of necessity possess the work. An inconsiderable number of new species are described.

The plates (only an uncoloured copy of the atlas is before us) are admirably executed, the drawings having been made by the author himself, and lithographed at Berlin, a course which has added greatly to their value, owing to the present impossibility of finding sufficiently skilled engravers in Buenos Ayres; at the same time it has naturally caused delay. The value attached to the beautiful representations of the transformations of many species, cannot be too highly estimated, and the explanatory text is very ample, containing also new matter, not appearing in the body of the work. R. McLachlan

MODERN METEOROLOGY

Modern Meteorology. A Series of Six Lectures Delivered under the Auspices of the Meteorological Society in 1878. (London: Edward Stanford, 1879.)

THE publication of "The Origin of Species" and the introduction of the spectroscope as an implement of research, have not wrought perhaps a greater revolution in the biological and physical sciences than has the invention of weather charts in the younger science of meteorology. One has only to look back a quarter of a century at the writings of meteorologists to see the radical change which has been brought about, not merely as regards the nomenclature of the science but even as regards the standpoint from which the whole phenomena of atmospheric movements are looked at. It was to diffuse more generally a knowledge of this change that the Council of the Meteorological Society arranged the delivery of these six lectures, which on the whole faithfully portray to the reader the present state of meteorology in its outstanding features.

From its important bearing on the future of meteorology in the British Islands, we note with great satisfaction the remark in the lecture on "Air Temperature" that the same pattern of thermometer box, viz., that known as the Stevenson, has been adopted at the stations of both the English and Scottish Meteorological Societies, to which may be added the stations of the Meteorological Office; and we heartily endorse the opinion expressed by the lecturer, Mr. J. Knox Laughton, that on such a vital subject as the observation of the temperature, absolute uniformity of pattern which is secured by the adoption of Stevenson's box, is better even than Utopian excellence.

The lecture by Mr. Strachan on the "Barometer and its Uses" is characterised by a full and exact knowledge of the instrument and its history, and a correct estimation of the present state of the problems relating to atmospheric pressure with which he has occasion to deal. His examination, for instance, of various theories which have been broached in explanation of the diurnal range of the barometer is acute and satisfactory, and from that examination he shows that a hypothesis yet remains to be framed which shall account for the diurnal oscillations of the barometer. The truth is, none who have yet attempted to account for the diurnal barometric oscillations—one of the widest spread and constant of terrestrial phenomena—have had before them sufficiently the facts of observation such as might indicate, with the requisite fulness of detail, the influence of geographical position on the problem which it is sought to solve.

Mr. Strachan throws out incidentally a valuable hint regarding the forecasts of our European weather which are wired from America. He says (p. 95):—

"It is worth while inquiring how our American friends manage this business. They are not very willing to show their hands, as the saying is. However, we may surmise how it is done. They have active agents who make extracts of the logs of all the steamers directly they arrive in New York, and by means of these extracts they can follow up all the storms which occur in our parallels. Thus it may often happen that information of storms is obtained by the *Herald* before they have had time to reach western Europe. The *Herald* at once flashes the news by telegraph. We get the telegram surely and speedily and the storm, if it does not vanish in the meantime, shortly afterward."

Whether this be the practice of the expert of the *New York Herald* or not, there cannot be a doubt that we have here an indication of the way in which substantial advance may be made in our system of weather forecasting, viz., by some central authority in America at once receiving by telegraph extracts from the logs of all vessels

directly they arrive at Atlantic ports; by the aid of which, warnings may be framed, and wired to Europe, of such storms as may appear to threaten its coasts. In this connection it is not possible to overestimate the importance of a telegraph wire to Farö and Iceland, by which warnings of many storms thus seen approaching our coasts, could be issued one or two days earlier at least than at present.

Mr. Clement Ley contributes an extremely interesting, and in some respects a very valuable lecture, on clouds considered as weather-signs, accompanied with nine well-executed illustrations in colours. Mr. Ley has been a close observer of the forms and movements of clouds almost from infancy, being even then strongly under the fascinating spell of their mystery and beauty. Habits of close and accurate observation were thus formed and the tendency has become so inveterate that to this day a twelfth part of his waking existence is spent in observing the clouds. For several years he has given the closest observation and study to a strict examination of the relations of different clouds to cyclones, anticyclones, and to thunderstorms, in other words, to changes of weather. It is the results of this examination which form the most valuable part of the lecture, these results being of the utmost importance to the isolated observer, who may take the trouble to follow up the subject, in enabling him with better success to forecast the weather though aided only by his own observations. A treatment of the subject with greater fulness than is possible in a single lecture would be warmly welcomed by meteorologists and all others interested in weather.

In one of the lectures it is stated with much emphasis that "the great need of every branch of meteorology is neither more observations nor more money (though neither of these is to be despised), but more brains, more hard workers, more deep thinkers." In a certain sense this is true, but in a wider sense it does not represent the most pressing needs of meteorology. In the last lecture of the series, Mr. Scott justly remarks that as regards synoptic work on a large scale, we may look our critics in the face and boldly ask for more observations, no matter how our shelves may be bending beneath the weight of undiscussed records. The truth is, those who are engaged with original researches in meteorology find themselves ever and anon seriously hampered, if not completely arrested in their work for want of the data of observation. We are unaware that any systems of observation at present exist which could furnish, for example, the data for the determination of the horizontal or vertical meteorological gradients, or for ascertaining how far and with what modifications the influence of the sea extends inland. Nay even, though thanks mainly to the indomitable energy of Mr. Symons, there are upwards of 2,000 gauges recording the rainfall of the British Isles, the number, not to mention positions, of these gauges, are too inadequate to admit of even a rude guess being formed as to the quantity of vapour abstracted from the air in the form of rain or snow during any of the storms that sweep across the country. Much less can we, without largely increased observation, give an indication of the varying hygrometric and thermometric states of the atmospheric currents to windward and leeward of the regions of large rainfall in Great Britain. Meteorologists, no less than astronomers, had cause to deplore a great loss in the death of Leverrier, the keenest sighted of physicists and prince of organisers of systems of observation, one of his last works being the establishment of a system of observation, by which the propagation of rain, hail, and other weather phenomena, could be followed from commune to commune over France. With such results as may be expected from this system, and from General Myer's magnificent scheme of monthly meteorological charts for the whole of the northern hemisphere, which will also bring into the field thousands of fresh observers, physical data leading towards the solution of some of the great meteorological problems will be supplied, without which observational data, mere brain-work—such is the complexity of the problems to be dealt with—would prove either useless or positively mischievous.

OUR BOOK SHELF

Farming for Pleasure and Profit. By Arthur Roland. Edited by W. H. Ablett. (London: Chapman and Hall, 1879.)

THIS small book has the defects as well as the merits which might have been expected in the work of an amateur farmer. His own practice seems usually sound and sometimes ingenious, but his explanations and advice cannot always be safely trusted. When he tells us what he has himself done, we listen with attention; when he offers us page after page full of antiquated veterinary nostrums, we cannot feel edified. We did not know till now that foot-and-mouth disease was *epidemic;* the cause and cure of apthæ (*sic*) is not quite adequately given on p. 205; and we should certainly hesitate before adopting the following treatment (p. 191) for a cow suffering from moor-ill:—"Some insert a seton in the dewlap and take away ten pounds of blood in very severe cases. A recipe has been given to administer, in very obstinate ones, six drachms of aloes, twelve ounces of sulphur, and sixteen drops of croton oil, the first day, in addition to a blood-letting of ten ounces," and so on with further directions of the heroic order. When Mr. Roland tells us of all the breeds of cows, of the cheese-factory system, and of a dozen other matters, of which, so far as we can learn, he has had no actual experience, we feel that his space and our time might have been more profitably occupied. That a good deal of information, and not a little amusement into the bargain, may be got out of Mr. Roland's book, is not to be denied, however. Whether "a great number of persons who would gladly supplement their incomes, if they could see their way clear to do it, by entering into rural occupations which are congenial to their tastes," would be able to follow the lead of Mr. Roland in his farming practice may be gravely doubted. It is not every amateur pig-feeder who will be so lucky as to find "a good pork-butcher, doing a superior trade, and ready to give nearly thirty per cent. more than could be obtained by selling young porkers haphazard." Nor will the amateur pea-grower always be able to adopt the following excellent and economical plan of disposing of his produce. Mr. Roland stows his green peas ready shelled in two flat wicker baskets under the first-class railway carriage in which he daily travels to town. He finds that the landlord of the hotel where he dines in the city will give him one shilling a quart for these peas, fetching them from the cloak-room of the station where they have been deposited. This ingenious method of marketing hardly admits, however, of general adoption; and, moreover, the railway authorities might have something to say about this plan of evading payment of carriage. Mr. Roland's previous attempts to dispose of cabbages and turnips (pp. 16 and 17) were less satisfactory in their

pecuniary results, though more accordant with ordinary experience. Let the reader of these eight chapters on "Farming for Pleasure and Profit" omit everything except what is given on the personal authority of the author, and he will gain a number of useful hints showing how to economise the vegetable food raised on a small farm, and to make amateur agriculture in some ways less financially disastrous than is usually the case. But we shall not find a complete system of practice here; nor do we discover any hints, however remote, of the chemical composition and physiological functions of food; and we look, too, in vain for any recognition of recent advances in our scientific knowledge as to methods of manuring and cropping.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Theory and Laws of the Microphone

Two hypotheses have been projected to explain the action of the microphone. One is molecular exclusively, and supposes that the molecules of certain conducting bodies contract and dilate under sonorous vibrations. Changes of *density* correspond with an increase or diminution of the resistance of the circuit. This hypothesis renders the phenomena analogous to those which selenium presents under the influence of light and radiant heat. The other explanation, partly mechanical and partly molecular, is the result of a discovery made some time since by M. du Moncel, according to whom the increase or diminution in resistance is due to changes of *pressure* at the points of electric contact. These changes of pressure are effected by the vibration of the air; hence the cause and the effect are similar.

As the result of numerous experiments, I shall endeavour to prove that, while one of these theories is altogether erroneous, the other is only superficially true.

1. If the piece of charcoal is fixed with wax without any pressure, the microphone remains silent under the strongest sonorous impulses, which would be impossible were the movement molecular.

2. The microphone may be inclosed in a vacuous chamber without altering the result; in this case waves of air can have no effect upon the density of the charcoal.

3. It is impossible to construct a microphone from one solid piece of charcoal, presenting stable contact, such as would not interfere with molecular action, but which prevents the sonorous waves from affecting the currents which traverse the carbon.

These afford sufficient reasons for rejecting any simply molecular theory.

Now against the second theory.

1. Lateral pressure on a compact electric conductor excites no microphonic action.

2. Longitudinal pressure within certain limits on the charcoal does not injure the apparatus.

3. An apparatus can be made to yield microphonic effects where there is no alteration of pressure. Pressure, therefore, is no essential cause of microphonic sounds, though it may be an accidental one.

In all microphones where contact is made at one point only, the current is interrupted whenever this point of contact is broken; a musical sound is heard when the two points are in vibration. This microphone, like Reis's telephone, can only transmit musical sounds. I have obtained the best results from a steel point and a membrane of a stretched bladder. A strip of tin-foil is gummed to the membrane to insure electric contact. With a single small cell of bichromate of potash a song can be heard through a whole room.

To transmit articulate sound it is necessary that the number of points of contact, the difference in this number during action, and the resultant changes of resistance, should be greater. The interruption of the current is then only partial; it becomes "undulatory." To this description belong the principal microphone of Mr. Hughes, Edison's carbon telephone, the transmitting telephone of two graphite pencils of MM. Pollard and Garnier, Helleren, &c.

A convenient form of microphone, which transmits words, music, the noise of a watch, &c., has the membrane of india-rubber stretched tight by a thin strip of tin-foil which unites the carbon underneath with the screw. The vibrations of the membrane throw a greater or less number of points into contact; all the shades of expression in the voice may be transmitted, owing to the rapidity of these small changes. It is the changes in the points of contact which here play the chief part, and there is little doubt that here we have the quality as well as the intensity of a sound reproduced.

This explains many of the microphonic actions, but not all. Here is one case:—

If the microphone is formed of two cylindrical pieces of charcoal, the points of contact cannot be made to vary by pressure, supposing the cylindrical shape to be perfect. The action here is due to the distance the current has to traverse the bad conductor; for the membrane to which these charcoal points are attached approaches or recedes from them when vibrating. The liquid telephone transmitters of Bell, Gray, and Salet rest upon the same principle where a change of resistance in the circuit is due to the varying depth of liquid traversed by the current. This, equally with the theory of the points of contact, explains the microphone of M. Righi, where a metallic disk is plunged into a powder of lead and silver mixed.

The next class of instruments consists of those where the current is created, and varies under the influence of microphonic electrodes (by this I mean the opposite parts of a microphone, whether in direct or indirect contact). Such are microphonic batteries. Each battery can act as a microphone if one of its poles is movable. Two ends of iron wire, dipped in ordinary water, and brought together, give signs of microphonic action. One pole is attached to the vibrating membrane, and dips at its extremity into the liquid, while the other pole remains there constantly. The current only passes when the movable pole is in the liquid. On singing into the tube the vibrations of the membrane cause the pole, which is also a microphonic electrode, to dip into the liquid, setting up chemical action as many times a second as there are vibrations in the note sung. If the pole touches the liquid constantly, the current is constant, but varies in intensity for four reasons: the different number of points exposed to electrolytic action; the different number of points of electric contact; the different number of the points of resistance of the liquid; and the different number of the points of approach of one pole to the other; all these are due to the movement of one of the microphonic electrodes.

There is yet another class of microphones. In all the instruments hitherto constructed, the direction of the current remains the same, but it is possible to make it change, thus introducing another difference in the manner of its action.

In all the possible forms of microphone, the chief causes of the action are:—a mechanical movement of its parts, a change in the points of conductivity, a change of resistance; these three essentials result from one another. The expression "points of conductivity" includes not only the points of contact, but also the route taken by the current.

The next point of consideration is the so-called increase of sound by a microphone, but this is not the case. All sounds are weakened by the microphone, and are transmitted only when the source of sound is in direct contact with the microphone or its stand. The microphone is less an instrument for transmitting sound than for transforming mechanical movement into sound. The intensity of a sound is, therefore, directly proportional to the energy of the mechanical movement accompanying the sonorous waves, or as a necessary consequence to the changes of resistance in the microphone. The distinctness of articulate sounds, transmitted by the microphone, is in inverse proportion to their intensity; for a loud sound tends to interrupt completely the current, and thus to prevent the transmission of articulate sounds. This is the chief hindrance to increasing, at pleasure, the loudness of the sound. The loudness of the sound is also dependent on the strength of the current.

Other experiments prove that the rapidity of movement of the parts of a microphone also affects very considerably the resultant sound, as well with a strong, as with a feeble current. Changes in resistance and in current strength are not sufficient, unless made rapidly, to excite microphonic action.

Great as is the invention of Mr. Hughes, the microphone reveals no new property of matter, neither does it show the direct effect of sonorous waves upon partially conducting bodies.

Lemberg University JULIAN OCHOROWICZ

"The Rights of an Animal"

I AM sorry that my review appears to have caused Mr. Nicholson some annoyance, but am not surprised that in his rejoinder he has not attempted to meet any one of my criticisms. As he now expressly avoids the well-known ambiguity which attaches to the word "same," he clearly avows his meaning to be what in my review I supposed it could not be, viz., that animals have "in all respects *identical* rights of life and liberty with man." If this proposition is seriously stated, it does not require a "writer capable of reviewing an ethical essay" to see that it cannot possibly have a place in any such essay, properly so called. And in supposing that this could not be the fundamental proposition which Mr. Nicholson intended to maintain, I did not "forget" that the animals which he allows "to be killed or worked were only allowed to come into life for these purposes." For if the rights of animals are *identical* with those of men, and if the breeding of animals for the purpose of killing them morally justifies the butcher in taking their lives, it certainly follows, for instance, that a physiologist would be morally justified in vivisecting his own children on the plea that it was for this purpose that he had begotten them. Where such is the necessary ethical conclusion, it is clear that the ethical premises by which it is evolved must be erroneous.

As regard the crustaceans, seeing that they are not "harmful animals," I chose them as a type of the class of animals which Mr. Nicholson plainly says it is in his opinion morally wrong to kill.

I may add that I omitted to mention the "plea" to which his letter in NATURE refers, because it had no relation to the opinion I was criticising—the opinion, namely, that harmless animals ought not to be killed for food. Here, however, is the "plea." "It may be answered that if none of these (*i.e.*, crustaceans) were killed more land animals would be killed for food; that their death allows more land animals to be kept alive for other purposes; and that this sharing of risks is only fair to the latter, the more so as they stand higher in point of intelligence and usefulness. Is this plea sound?" I can scarcely suppose that Mr. Nicholson will thank me even now for reproducing so feeble an argument, and in any case am quite sure that the latter, whatever it is worth, has no reference to the abstract principle which I was examining.

The relevancy of Mr. Nicholson's "protest" I fail to perceive. That "principle" and "self-interest" are not synonymous is sufficiently obvious, but I do not see how this consideration affects my charge of "inconsistency of principle." I simply pointed out that if we have a moral right to slay a harmful animal in order to better our own condition, it involves an inconsistency of principle to deny that we have a similar right to slay a harmless animal, if by so doing we can secure a similar end. And this obvious criticism is not affected by the irrelevant remark that "principle" and "self-interest" are not synonymous.

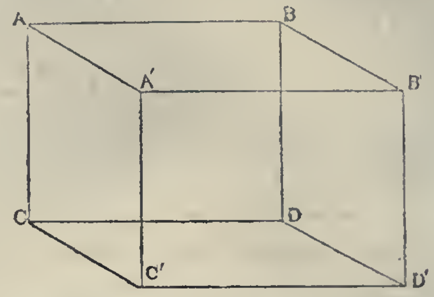
Again, as I was reviewing Mr. Nicholson's essay, and not Mr. Lawrence's book, I deemed it unnecessary to allude to the "reprints" from the latter, more especially as I saw nothing in these reprints of a nature either "interesting" or instructive. If my omission in this respect is calculated to damage the sale of the essay which I reviewed, I can only express my sorrow that such should be the case; but as I further omitted to state that the pages of the essay are small and very widely leaded, the idea which I conveyed of the size of the book as a whole was certainly not an inaccurate one.

I have taken the trouble to reply to the above remonstrance thus fully because I am conscious of having done what every honest reviewer ought to do, viz., to state what he thinks and to give his reasons for what he states. But as the result in this case has been to dissatisfy the author reviewed, I think it is now desirable to prove, by subscribing my name, that I have no personal *animus* against him. GEORGE J. ROMANES

A Suggestion on the Action of the Oblique Muscles of the Eye-ball

THE action of the so-called oblique muscles of the eye-ball has been a *quæstio vexata* amongst anatomists for a long time, but I, in all submission, venture to suggest the following experiment which *may* be entertained mathematically. I speak of my own eyes, and the method in which I endeavour to use my oblique muscles, according to authorities.

Suppose I draw a skeleton cube at haphazard thus—



and I *concentrate* my vision on the anterior plane of this cube (A′ B′ C′ D′) in the sketch; if I put in action (according to what we believe to be the action) the superior and inferior oblique muscles, the projection is immediately altered, and the plane A B C D is instantly the anterior? Pardon my apparent ignorance of physics, but may not some of your many correspondents, without ignoring my anatomical knowledge, make the statement a basis for research. A good explanation for the condition I must confess has escaped me?

It may throw some light on the question as to whether the oblique muscles definitely alter the optical functions of the eye, which is certainly a matter of the greatest practical interest.

EDWARD BELLAMY

Natural History Notes from Burmah

1. *The Dorian.*—The Dorian is a large capsular fruit with four or five loculamenta, each containing one seed which is covered with a layer of pulp, the part eaten. The rind, as well as the seeds, emits a strong odour of sulphide of methyl.

Dorian eaters say that the excellency of the fruit consists in the succession of exquisite flavours experienced in eating it. From my own experiments I believe this to be due to a reaction of the nerves of taste, analogous to that of the retina, which causes the images of objects to appear in their complementary colours when the eye is suddenly shut.

2. It is asserted that the weaver bird has the habit of fixing fire-flies to the side of its nest by means of a lump of mud, for the purpose of illuminating its nest at night. I have not observed it myself. Perhaps some of your readers may have seen or heard of the practice.

3. *Ants.*—There is here a species of small black ant, of which there occur gigantic specimens differing from the others only in size. They seem to act as the elephants of the community, carrying loads that the small ones cannot lift. Sometimes one of these "elephants" may be seen returning to the nest with several of the ordinary size clinging on its back.

Once while taking lunch in the image cave at Maulmain, we observed several large black ants wandering about. A chicken bone thrown in their path was soon discovered, and a messenger was despatched to the nest, from which a compact body of ants soon issued. But by some mistake they took the wrong direction from the nest, and proceeded towards a fragment of plaster that had fallen from one of the statues and lay on the floor of the cave. This they examined all over, and then returned to the nest in a less orderly manner than they had marched out, but at the entrance some other ants met them, who must somehow have given them the proper direction, for they at once changed their course towards the bone, which was soon covered with ants. I think this observation has some bearing on the way in which ants communicate. It is clear that the messenger's signs were misunderstood, and they went so straight to the bit of plaster that it appeared to me that they must have seen it, for sight is the only sense that could have been deceived. The distance was about four feet, and this occurred near the entrance to the cave, so there was light enough if their range of vision was great enough. R. ROMANIS

Government High School, Rangoon

Pigeons and Weather Warnings

In the *Standard* of the 5th instant is an account of a pigeon-race from Penzance to London, a distance of 270 miles, which was done by one bird in 5 hours 34 minutes, and by another in 5 hours and 59 minutes. Might not the carrier-pigeon be employed to bring accounts of the weather 300, 400, or even 500 miles out in the Atlantic, being despatched on outward voyages by ships leaving ports such as Queenstown, Southampton, Dartmouth, Plymouth, or Falmouth? The great difficulty in our system of weather-warnings is that storms reach us unannounced over the Atlantic, because stations are of course out of the question on the ocean. If the daily sailings of steamers from various ports could be utilised by means of pigeons, this void might to some degree be filled. If it be true that many storms come to us along the course of the Gulf Stream, a branch of it (Rennell's Current) would be met a little beyond the Scilly Islands, say 100 miles farther out, or about 150 miles from Falmouth. If a bird brought a weather-warning in three hours from what would appear to be an important point, it would surely advance matters a good deal. A great part of England can be warned from the Irish coast, but Scotland has no advance-guard of this sort. Steamers leaving Greenock for America could carry pigeons and send warnings back, thus giving Scotland some protection. R.

Putney, August 5

Napoleon III. and the Nicaraguan Canal

At p. 249 of Nature, vol. xx. it is made to appear as if the circumstance of the connection of the late Emperor of the French with the scheme of Central American canalisation through Nicaragua, was *quite unknown* to the public. But it is well known that Prince Louis N. Bonaparte, whilst at Ham, was in communication with Don Francisco Castillon, envoy to Louis Phillippe from the Nicaraguan Government upon this subject. After the escape of Louis Napoleon from France, he publicly advocated the project of the Nicaraguan Canal at the Institution of Civil Engineers, London. (*Vide Proceedings* I. C. E., 1847, vol. vi. p. 427; *vide* "The Gate of the Pacific," by Commander Bedford Pim, pp. 118, *et seq.*) S. P. O.

Vitality of the Common Snail

At the beginning of July last year, I placed a couple of the *Helix aspersa* into a closed pot of earth immediately after copulation. They soon sealed themselves up, and so remained till the middle of May of this year, when it was discovered that of one of them that had died not a vestige was left except the empty shell. The other had shrunk to about a third its former bulk, but on being moistened and supplied with food, soon began to eat and to thrive. It had to trust largely to chance for its provender, but notwithstanding this, by the end of two months it was as big as its present quarters would allow it to be. The natural thing would have been to secrete more shell, for the animal was not full grown. Instead of this, however, it burrowed in the ground, and fell to laying eggs, the greater part of which have hatched out—a little colony of vigorous young snails. Had their parent been kept supplied with food and water after impregnation, they would, of course, have begun life a year ago. I wonder how high up in the animal scale such temporary suspension of the earliest stages of development is possible?

Trinity College, Cambridge, August 7 James Ward

OUR ASTRONOMICAL COLUMN

Variable Stars.—It may be hoped that some amateur in the other hemisphere—the class of observation is hardly suited to the professional astronomer, considering the work that remains to be accomplished in the southern heavens—may be keeping in view Lacaille's star, μ Doradûs, which is certainly variable to a great extent, and in a very long period. In the Catalogue published by the British Association founded upon the observations in Lacaille's *Cœlum Australe Stelliferum*, the star is rated 5 m., though in the Catalogue at the end of this work we find it 6 m., the estimate applying to the year 1751, and this is also the magnitude noted by Brisbane about 1825. The variability of the star was first shown by the late Capt. Jacob's observations at Madras early in 1850; he found no such conspicuous star as Lacaille and Brisbane had observed, but fixed the position of one which nearly agrees with the Paramatta place, and which was estimated 9·5; this star was reobserved at Madras in 1855 and rated 9·2. The next we hear of it is from Moesta, who, observing at Santiago, states (*Astron. Nach.*, No. 1,545) that from February, 1860, to January, 1865, he had found it 8½ or 9 on Argelander's scale. Finally Mr. Stone observed the star at the Cape of Good Hope in 1875 and estimated it a *seventh* magnitude, which should induce a close watch upon it at the present time. The star was formerly credited with a very sensible proper motion, but it would appear from the modern observations that this arose from an error in Lacaille; thus, bringing up all places to 1875·0 we have—

				Right Ascension. h. m. s.		North Polar distance. ° ′ ″
Lacaille	1751	December	...	5 6 2·2	...	151 57 3
Brisbane	1825		...	5 5 51·42	...	151 57 55·2
Jacob	1850		...	53·16	...	59·3
—	1855		...	53·34	...	57·0
Stone	1875		...	52·74	...	59·3

There appears a suspicion of a similar case with regard to the star Brisbane 5935, observed once at Paramatta and estimated 6 m. This star does not occur in Lacaille, but it was looked for in 1850 by Jacob, who found only one 9·10 m. near the place given by Brisbane, differing however 4s. in R.A. and 1′ 18″ in N.P.D. Mr. Stone's nearest star is Lacaille 7093. If the objects observed by Brisbane and Jacob are identical, proper motion as well as variability will enter into the case.

The observations of Julius Schmidt at Athens in 1878 again show great irregularity in the variation of R. Scuti, the mean period he obtained for that year being 62·3 days, instead of 71·1 days, as determined by Prof. Schönfeld, and which was satisfactory in 1869. The last epochs determined at Athens in 1878 were, for a maximum, November 8, and for a minimum, October 11. The mean period of α Herculis in the past year was found to be 97·3 days, but the period varied from 86 to 113 days. In such instances it is obvious that observations, made as continuously as possible can alone determine whether the fluctuations follow any definite law.

The Minor Planets.—The discovery of a small planet by Prof. Peters at Clinton, N.Y., on July 28, raises the number of known members of the group to *two hundred*, the object detected by the same astronomer on July 16 proving to be an old acquaintance,—No. 77 (*Frigga*), which had not been recognised for upwards of ten years. Of the planets discovered during the present year, No. 193 (Coggia, February 28) has been named *Ambrosia*, No. 196 (Peters, May 17), *Philomela*, and No. 198 (Borrelly, June 13), *Ampella*.

The Satellites Mimas and Hyperion.—According to elements which have been previously used in this column, *Mimas* would be found at its greatest eastern elongation on August 20, at 13h. 47m. G.M.T., distant 30″ from Saturn's centre or 8″ from the extremity of the ring; the period of revolution may be assumed 0·94243d. It appears difficult to make reliable prediction of the position of *Hyperion* from present uncertainty as to the motion of the line of apsides. Prof. Asaph Hall adopts a retrograde motion of less than 3° annually, but there are indications that the true motion may be in the opposite direction, and to a much greater amount. Mr. Marth, who has devoted so much time and labour to the motions of the satellites of Saturn, was of opinion some ten years since that the revolution of the line of apsides of *Hyperion* would be found to be very rapid, through the powerful action of the great satellite *Titan*. Three periods of *Hyperion* are almost exactly equal to four periods of *Titan*, if we adopt Prof. Hall's period for the former.

GEOGRAPHICAL NOTES

On August 1 the International Conference of the Alpine Clubs was opened at Geneva, in the building of the Conservatorium. The Alpinists were very numerous, and the meeting was really an international one, as all nations have sent their representatives. M. Albert Freundler occupied the chair, and Mr. C. E. Matthews, president of the English Alpine Club, Prof. Talbert, vice-president of the Central Directory of the French Alpine Clubs, M. Budden, from Florence, Prof. Ed. Richter, delegate of the German and Austrian Alpenverein, and Prof. Charles R. Cross, from Boston, were elected vice-presidents. The subjects submitted for discussion were: 1. The improvements to be made in Alpine inns; 2. The regulations concerning shelters; 3. The instruction and examination of guides; 4. The possibility of a common action of the Alpine Clubs for obtaining from the railway companies a reduction of fares for Alpinists who travel in groups; and 5. Sanction by all clubs of the resolutions passed by some of them as to inns and guides. The discussion was alternated with communications of a more general interest. M. Henri de Saussure read a communication on the state of the Boston (U.S.) Appalachian Club, whose activity is remarkable as shown by numerous publications of a high scientific and artistic value. In the discussion on shelters M. Binet-Hentsch proposed to make the roofs of the Alpine shelters of bituminated paper; the experiment which was made by the government of the canton of Graubunden, proves these roofs to be excellent. M. Durier gave a brilliant account of his exploration of Etna, which he made eight months before the eruption of this year. The Rev. M. Denza, director of the Observatory of Moncalieri, read a paper on mountain meteorology. The memoir, which aimed to interest Alpine climbers in meteorology and to point out the services they could render to science during their travels, gave an account of what is done by Italian Alpine Clubs for meteorology, no less than one hundred meteorological stations having been erected by these clubs, fourteen of them at very high altitudes. The memoir gave rise to a very interesting discussion, during which Prof. Alphonse Favre spoke of the necessity of measurements of the motion of glaciers; and the Italian and Austrian representatives explained what is done in that direction in their countries. M. Henri de Saussure read three unpublished letters, written to his illustrious ancestor, Horace Bénédict de Saussure, as to his ascent of Mont-Blanc. The papers of that time having spoken of his project, his friends wrote to him numerous letters to dissuade him from the perilous undertaking. The Abbé Landriani entreats him in the name of science to take care of himself, and not to risk his precious life, and the Prince de Ligne, a very gallant officer, advises him to undertake a regular siege of the giant mountain; several relays of workmen, with pick-axes and shovels, should "level the asperities of the road, and so," he writes, "going up some ten fathoms per day, you could reach the summit after a six weeks' work." As to the instruction and the examination of the guides, M. Talbert recommends such institutions as that of Interlaken, in Switzerland; besides, he proposes to found libraries for the guides and to publish a manual like that just issued by the president of the Italian Alpine Club. As to the reduction on tickets, the French railways have made a reduction of fifty per cent. for all Alpinists travelling either in groups or separately, so that no less than 130 members went to the Conference of Geneva. No special resolution was taken on the fifth question, but it was resolved to maintain an active correspondence between the directors of all Alpine Clubs.

The *Times* Berlin correspondent telegraphs that news has been received that Prof. Nordenskjöld has succeeded in getting out of Behring Straits. We are inclined to doubt the accuracy of this statement; we have reason to believe, at least, that no such news has been received by Mr. Oscar Dickson, of Gothenburg, who would most likely be the first to whom Nordenskjöld would communicate his success.

The efforts which Commander Cheyne has been making for some time past to organise a new Arctic Expedition promise to be successful. Committees have been established all over the country, with a central Arctic committee in London, located in the rooms of the Literary Society. Lord Derby has subscribed 100*l*. towards the expedition, and his example has been followed by Mr. Samuel Budget. We believe that balloons will form an important part of the equipment of the expedition. The Bank of England, it is stated, has consented to open an account under the title of "The New British Arctic Expedition."

Two well-known African travellers will again start for the Dark Continent during the autumn: Dr. W. Junker will visit the Egyptian Soudan, while Dr. Oscar Lenz, the eminent Ogowe traveller, will go to Morocco by order of the German African Society. This society is making arrangements to establish in Morocco a school for African travellers, as it were; the country, although comparatively near, being yet very scantily investigated. Moreover, the young travellers will there get thoroughly accustomed to Mohammedan life, and the Society will thus acquire well-trained representatives to be sent afterwards to various parts of Central Africa.

The Admiralty have issued a hydrographic notice respecting the Siam coast in the Bay of Bengal, the information in which is derived from the notes of Commander A. D. Taylor, Superintendent of the Marine Survey of India, and from remarks by Commander A. de Richelieu, of the Siamese Navy. Among other items of geographical information contained in it, we learn that the town of Takuapah is situated on the Takuapah or Kopah River, in the Siamese province of Muang Takuapah, in 8° 48′ N. lat., about fifteen miles from the sea. It is surrounded by tin mines and large plantations, and its inhabitants are mostly Chinese. The only export is tin, of which a considerable quantity is sent away, and indeed, next to Puket, it is the largest tin-exporting place on the coast of Siam. The houses are mostly of bamboo and atap, though some few are built of brick. There are several mining villages along the banks of the river, and the country about Takuapah and to the northward is undulating and mountainous. Pia Sima, the highest mountain, about ten miles east of Koh Rah, culminates in three peaks of nearly equal elevation, and is upwards of 3,500 feet above the sea.

We understand that a work by Mr. V. Ball, of the Geological Survey of India entitled "Jungle Life in India, or the Journeys and Journals of an Indian Geologist" will appear shortly. The volume will contain a popular account of the author's observations, extending over a period of fourteen years, on the geology, zoology, botany, and ethnology of Western Bengal, the Central Provinces, the Himalayas, Beluchistan, and Afghanistan, the Andaman and Nicobar Islands, and Burmah, interspersed with which are numerous anecdotes and sporting adventures. A number of beautifully executed woodcuts and a map, the former illustrative of the scenery and inhabitants of these comparatively little-known regions, will aid, it is believed, in commending the volume to a large and varied circle of readers. In a series of appendices some of the more strictly scientific topics are dealt with. The publishers are Messrs. Thomas De la Rue and Co.

Recent news from South Australia states that a plentiful supply of fresh water has been obtained on the tube-well principle on the Mount Lofty Range, 1,700 feet above the Adelaide plains.

A PARAGRAPH recently went the round of English and foreign papers and geographical journals, purporting to give the population of Japan according to a census taken in 1878. We have the best authority for stating that no census has been taken in Japan since 1875, and that the numbers given as for 1878 were really those of 1875.

NORDENSKJÖLD'S ARCTIC EXPEDITION

LETTERS have just come to hand from the Swedish North-east Passage Expedition in the neighbourhood of Behring Straits. The latest date is February 20, when all was as well as possible. We take the following details from Prof. Nordenskjöld's report, addressed to Mr. Oscar Dickson, of Gothenburg. The *Vega* and the *Lena* parted company on August 27 at the mouth of the River Lena, the former shaping her course for the New Siberian Islands. The air was calm, but for the most part overcast; the temperature as high as 4° C., and the sea free from ice. On the 28th Semenoffskj or Stolbovoj, the most western of the New Siberian Islands, was sighted, and on the 30th Liakhoff's Island, but a landing was not effected on account of the shallowness of the water in its vicinity. On the 31st Svjatoi Nos was passed without difficulty, the weather being fine, and the land in the neighbourhood free of snow. The water was slightly salt, and had a temperature rising to 4° C. The weather continued fine until September 1, the wind being southerly, and the temperature of the air in the shade 5·6° C. On the night before the second the wind became northerly, and the temperature fell to – 1° C. The following night there was a large fall of snow. Next day the Bear Islands were reached. Tschaun Bay was passed on the night before September 6, and Cape Schelagskoj reached by 4 A.M. The nights now began to be so dark, and the sea so filled with ice, that the *Vega* had to lie-to at night, generally anchored to a large ground ice. Two boats resembling the *umiaks* of the Eskimo were now seen filled with natives, the first that had been encountered since the expedition left Chabarova at Jugor Schar. They were received in a friendly way, but none of them could speak Russian or any other language intelligible to the Swedes. A boy could, however, count ten in English, showing that the intercourse with American whalers was greater than with Russian merchants. On September 6 and 7 the *Vega* steamed slowly along in a narrow open and ice-free channel along the coast. On the 8th a landing was effected near a Tchuktch encampment, where the Swedes were received in a very hospitable manner. They found in one tent reindeer flesh boiling in a large pot of cast iron. Another start was made on September 6, but a fog compelled the Swedes to lie-to till the 10th. Many excursions were made on land. The strand was formed of sand which, immediately above high water-mark, was covered with luxuriant turf. Farther inland, a range of very high hills was visible, and beyond that, at a considerable distance from the coast, snow-covered mountain-tops. The low land consists of sand and clay beds, evidently raised above the level of the sea very recently. No erratic blocks were to be seen, from the absence of which Nordenskjöld concludes that there is not at present to the north of this any such glacial land as Greenland. The rocks here were non-fossiliferous. Few land plants could be collected on account of the advanced season of the year, and in the sea Dr. Kjellman dredged for algæ in vain. On land many graves with burned bones were found. On the night before September 10 the sea was covered with a very thick crust of newly-frozen ice, but the *Vega* continued her course. On the 12th, after passing Irkaipi, or the North Cape, the vessel had to be anchored to a block of ice, where she lay till the 18th, when another advance was made. After lying-to from September 24 to 26, the *Vega* reached Cape Onman, and on the 27th Koljutschin Bay. The following day the cape to the east of this bay was passed, and the *Vega* lay-to, anchored to a ground ice, waiting for a favourable change, but no such change took place. Northerly winds heaped greater and greater masses of drift ice along the coast, and soon extinguished all hope of getting free before the summer of this year.

SIR THOMAS MACLEAR, F.R.S.

THE last Cape mail brought intelligence of the death of Sir Thomas Maclear, which took place at his residence, Mowbray, near Capetown, on July 14.

Sir Thomas Maclear was a son of the late Mr. James Maclear, of the County of Tyrone, and was educated at Winchester. He was originally destined for the medical profession, but, after settling at Biggleswade, we find him occupying himself in astronomical pursuits. He joined the Astronomical Society in 1828, and erected a small observatory at Biggleswade, which contained the Wollaston telescope, lent by the Society, with which he observed many occultations and other phenomena. He also engaged upon astronomical calculations, chiefly for the prediction of occultations. In conjunction with Henderson he computed the circumstances of the occultations of Aldebaran for ten European observatories in 1829–31, and himself calculated such of the occultations in 1833, about 100 in number, as were visible at Greenwich, for the supplement to the *Nautical Almanac* of that year. On Henderson's retirement from the direction of the Royal Observatory at the Cape of Good Hope, Maclear was appointed his successor, and entered upon the office in January 1834. Of the great number of observations made during his superintendence a portion only have as yet been published. He entered upon an undertaking of the importance of which there cannot be two opinions—the verification of Lacaille's arc of the meridian, but it was allowed to disorganise the regular work of the observatory to a serious extent. The observations by Maclear and his assistant in 1834 were speedily reduced and published, and various series of observations of comets when beyond reach at the northern observatories, have appeared in the *Memoirs* of the Royal Astronomical Society, where also have been published his determinations of the parallax of α and β Centauri, the latter of which had not been previously investigated, and there are memoirs on other subjects. The field work for the re-measurement of Lacaille's arc was completed in 1847, but from various delays the results were not published until 1866, when they appeared in two quarto volumes, under the editorship of Sir George Airy. The time occupied upon this work prevented the reduction and publication of the meridian observations; so that on Mr. Stone's arrival at the Cape in 1870 (as successor to Maclear on his retirement) he states he found himself "confronted with the results of thirty-six years of miscellaneous observing, in all stages of reduction."

Acting upon his official instructions Mr. Stone completed the reductions and published in several volumes the results of the observations with the new transit-circle from 1856 to 1860 inclusive; there remain still unpublished the observations from 1834 to 1855 with the old instruments, and those from 1861 to 1869 with the new one. Of the large number accumulated in the former period, the places of southern stars will still be of value for proper motions, but Mr. Stone has expressed a doubt whether "the immense number of observations of well-known stars" made with the old instruments would now repay the labour of reduction.

Maclear was knighted in 1860. He had been a Fellow of the Royal Society since 1831, and was elected a Correspondent of the Institute of France in 1863 in place of the American astronomer Bond; in 1867 the Lalande medal was awarded him by the Academy of Sciences, and in 1869 he received one of the Royal medals annually adjudged by the Royal Society.

We are informed that at Sir Thomas Maclear's funeral, on July 16, all the principal residents in the colony were present. The Cape Parliament has passed a resolution or memorandum acknowledging the work he did for the colony.

A POINT AFFECTING THE DIFFUSION OF THE GASES OF THE ATMOSPHERE IN RELATION TO HEALTH

THE great importance in relation to health of the part played by the internal motion of gases, as indicated by the now established and admirably simple kinetic theory, would seem scarcely to receive adequate appreciation. The old and vaguely developed statical idea of a stagnant atmosphere with molecules at rest, has given place to the opposite view of a high activity of motion, even when the atmosphere appears to the senses to be still. By this motion noxious vapours or gases, instead of remaining stagnant, are rapidly scattered by diffusion, and thereby rendered harmless. The part apparently played here by inequality of molecular *velocity* (dependent on inequality of molecular mass) in contributing to this end, would seem scarcely to have received the attention it appears to deserve. In Prof. Tait's work, "Lectures on some Recent Advances in Physical Science" (p. 237, second edition), reference is made to the diffusion of the gases of the atmosphere under the kinetic theory, and here it would seem as if the influence of the *inequality* of the normal velocity of the molecules of the different gases of the atmosphere (dependent on inequality of molecular mass) had not been taken into account, and hence it would appear as if the gases in their mutual diffusion were regarded as subject to the pure contingencies of chance, as they would be if the velocities of the molecules were equal (or their masses equal); this necessarily leading to some rather startling conclusions, which make the continuance of life and health (as dependent on the equable mixture of the constituents of the atmosphere) a matter more or less dependent on contingency or accident. The passage in question runs as follows :—

"There is another extremely important point of this statistical question as to the particles of gases which I must carefully explain; and it is this, how it happens that in the enormous bulk of the whole atmosphere of the earth these particles of oxygen and nitrogen, moving about amongst one another, should not by chance, at some place or other, operate on one another in such a way that in some particular cubic inch the particles of nitrogen might for a moment expel from it all the particles of oxygen, so that in virtue of the great extent of the earth's atmosphere, compared with the size of a particle of gas, there might be at some definite instant a region filled mainly with nitrogen, and other regions filled mainly with oxygen. Now the beauty of this statistical method is that it explains to us how such an event, though perfectly possible, can never occur. It is a thing which is itself absolutely possible, but it never can occur in practice, because the probability of its occurrence is so exceedingly small. There is a probability (numerically measurable) for everything which is possible, but if that probability (reckoned in numbers) is as small as the probability of the accident we are considering, we never expect to find it occur. And not only do we never expect to find it at any time, but we can say boldly from experience that it is never met with at all, however long our observations are conducted, or through however great an extent of space we conduct them. If you had originally in a box divided into two equal parts, nitrogen in the one part and oxygen in the other, and then allowed them to mix with one another, the probability that in any assigned time you could find all the nitrogen back again in the space where it was originally, and all the oxygen back again in the space where it was originally, is certainly one which can be measured, but it is one which is so infinitesimally small that we know perfectly by experience that it can never be realised."

The above appears a somewhat unsatisfactory conclusion to contemplate, and there would seem to be something scarcely consistent in the inference that an event which is itself absolutely possible never can occur in practice, "because the probability of its occurrence is so exceedingly small." For we know from the doctrine of probabilities that an event of chance (if possible at all) *must* occur, if the range of time be not restricted, or at least its probability approaches with *indefinite* closeness to absolute certainty in that case. That the probability, for example, of suffocation in a room [taking the above illustration of a box on a large scale] within a given range of time, by the oxygen separating itself sufficiently from the nitrogen, could be rigidly calculated, seems scarcely pleasant to contemplate, however remote the contingency might be, and it is hardly satisfactory to think that the contingency of such an event approaches with indefinite nearness to absolute certainty if an adequate *time* be conceded. The very fact that considering the vast extent of the atmosphere and the range of historic time, no record whatever exists of any irregularity having been detected in the constitution of the atmosphere, would surely be strong argument for the existence of some physical cause tending to prevent such irregularity from occurring, and removing it from the pure contingencies of chance. The above quotation that—"we can boldly say from experience that it [*i.e.* the irregularity] is never met with at all, however long our observations are conducted"—would surely tend to prove that some preventive means existed.

If the molecules of nitrogen and oxygen of a mass of air confined in a room were supposed subject to the pure contingencies of chance in their mutual actions in diffusion, they would be comparable to a number of equal perfectly elastic black and white balls imagined to be moving and colliding freely among themselves, or left to their own dynamics in an analogous manner. In this case there would evidently be practically an infinite number of chances against the molecules of the two gases (represented by the two differently coloured sets of balls) from becoming uniformly diffused through the room; indeed the probability of this event would be exactly the same as the probability of the oxygen being all separated in one part of the room and the nitrogen in the other (or in analogy all the black balls separated from the white); for we know that, according to the doctrine of probabilities, every *assigned* arrangement for all the balls is equally probable.

I venture to suggest that the inequality in the *mean velocity* of the molecules of the two gases (dependent on the inequality of the masses of the molecules) plays an important part here. If this particular point has been considered elsewhere (without my knowledge), I may still perhaps give an elementary analysis of the problem, as it has occurred to me. It may be remarked that on account of the simplicity of the kinetic theory, its problems frequently admit of elementary treatment, and it will at least be admitted that wherever this is practicable, perspicuity does not lose thereby. We will imagine for illustration a portion (say spherical shaped) of pure oxygen gas to be at a given instant of time surrounded by an atmosphere of hydrogen. [We may neglect the existence of gravity, for simplicity, as it does not affect the point with which we have to deal.] Then diffusion at once commences. The molecules of hydrogen which have one-sixteenth less mass, are known to possess a normal velocity four times that of the molecules of oxygen. The molecules of hydrogen by their own normal motion will therefore rush into this spherical space occupied by the oxygen, four times as fast as the molecules of oxygen can move out by their natural motion. Owing to this inequality in the rate of exchange of places of the two gases, the mass of gas occupying the spherical space will begin to increase in density, and (for

a converse cause) the gas surrounding the spherical space will diminish in density to a corresponding amount. This initial irregularity of density will cause an initial irregularity of pressure, which will tend at once forcibly to readjust itself, and will do so by the gaseous mixture within the spherical space expanding,[1] and an exchange of energy (or "heat") taking place between the two gases—which abnormal state of things can only cease when the two gases become uniformly mixed, and consequently the dynamical conditions become symmetrical in all parts of the mixture. Owing to the absence of dynamical equilibrium in the case of two gases having different molecular velocities, *unless* the gases are uniformly mixed, there is therefore a forcible dynamical tendency to produce uniform mixture, and to maintain it against disturbing causes, when once the mixture has become uniform. When the molecules of the two gases possess unequal normal velocities (attendant on inequality of mass), it is evident that the distribution of velocities can be symmetrical throughout the mixture, *only* in that case where the mixture is uniform. If, on the other hand, the molecules of the two gases possessed the *same* normal velocities (due to equality of molecular mass), there would be no dynamical cause for any particular mixture more than another, or every assigned mixture (regular or irregular) would be equally probable: for the distribution of the velocities would be symmetrical or uniform, whatever the mixture might be. Taking our illustration of the spherical portion of gas, and supposing the gas surrounding it (though chemically different) to have *equal* molecular velocity, then the exchange of molecules between the gases would take place at the same rate, and consequently there would be no disturbance of the equilibrium of pressure at all, but one mixture would be as possible as another, and the distribution of the velocities would be symmetrical whatever the mixture might be.[2] In fact, it would resemble the case of the diffusion of two portions of one and the same gas into each other.

Thus it would appear that the fact of the molecules of the constituent gases of the atmosphere possessing unequal normal velocities (due to inequality of molecular mass) tends, through the dynamic action of the molecules, to produce and maintain forcibly a uniform mixture of these gases, and to prevent those detrimental irregularities of mixture that would inevitably occur (by a sufficient range of time and space), if the constituent gases of the atmosphere were of *equal* molecular masses, and consequently diffusion were brought under the pure contingencies of chance.

I have ventured to call attention to this point from its apparent importance, and as the passage above quoted would have the appearance at least of treating the problem as one of pure chances, or as if the influence of the *inequality* in molecular velocity had not been taken into account, but I shall be glad to accept correction if I am wrong.

The fact of the two gases of the atmosphere possessing unequal molecular masses would evidently seem to be of importance as a means for scattering and thereby rendering harmless, noxious vapours and gases which are emitted into the atmosphere. For even if the particular vapour (in a rare case) happened to be of the same molecular mass as one of the constituents of the atmosphere, it must differ from that of the other constituent, and thus a dynamical cause for dispersion exists. The considerable inequality in molecular mass of the most prevalent deleterious ingredient emitted in combustion and in the course of animal life (carbonic acid) thus ensures its dispersion.

In a paper published in the *Phil. Mag.* for April, 1875, by Lord Rayleigh—"On the Work that may be gained during the Mixing of Gases"—it was pointed out that work may be derived from gases in an unmixed state, and a special method for effecting this end was described. In two papers communicated by me to NATURE (vol. xvii. pp. 31 and 202), I, being at that time unaware of Lord Rayleigh's memoir, indicated a simple mechanical means of deriving work from unmixed gases by the use of porous diaphragms. If we imagine a cylinder, into the piston of which a disk or diaphragm of some porous substance (say plumbago) is fixed, and that two gases of unequal molecular masses (oxygen and hydrogen, for instance) are introduced into the opposite compartments of the cylinder, then diffusion commences in the known manner through the porous diaphragm. Owing to the inequality in the normal velocities of the molecules of the two gases, they pass through the pores of the diaphragm at unequal rates, thereby entailing an inequality of pressure on the two sides of the diaphragm. If then the piston (containing the diaphragm) be suddenly released, it will be driven towards the opposite end of the cylinder, and work may thus be derived. [A simple automatic device for continuing the work by a constant supply of gas was described in NATURE, vol. xvii. p. 204.] Although the work is here derived in a self-acting manner, solely at the expense of the normal temperature heat possessed by the gas, yet this would not apparently be out of harmony with the second law of thermodynamics [as the writer at first supposed]; for it appears that for such to be the case, the process would require to be a *reversible* one, or the gases would require to be restored again to their original unmixed state. But if it were possible that the gases could effect this themselves, or become unmixed by their mere action upon each other, and the probability, that in any assigned time we should find all the oxygen back again in the one half of the cylinder, where it was originally, and all the hydrogen back again in the other half, is one which can be measured (however remote this probability might be); then we should have a possible means of deriving work at the expense of normal temperature heat by a process that was self-reversible. Hence this result to which we are led would serve to confirm the above view, viz., that when gases are of *unequal* molecular masses, there is a forcible dynamical tendency to keep them mixed, or to prevent the gases from becoming separated again when once they have become mixed.

There would seem to be another consideration bearing directly on the above case. It was a law enunciated by Dalton that when gases of different kinds are placed in the same vessel, "each gas behaves to the other as if it were a vacuum." This, when viewed by the light of the modern dynamical theory, is no doubt true as regards the fact that the total pressure on the sides of the vessel is the sum of the pressures which each gas would exert independently if placed by itself in the vessel. But if the expression "that one gas behaves to another as a vacuum" were taken to refer to the *arrangement* of the gas in the vessel, then some modification would appear to be required in the statement of the law in the case where the different gases are of *equal* molecular masses (as also where portions of gas of the same kind are successively introduced into the vessel). For it appears from the above considerations that gases do not *necessarily* become uniformly mixed by the action of diffusion, excepting when the gases are of *unequal* molecular masses. For portions of gas of equal molecular masses behave to each other as portions of gas of the same kind. If we imagine (merely for illustration) the molecules of a portion of gas to be *marked*, and this portion of gas to be introduced into a vessel where already gas of the same kind exists, then it is evident that there

[1] The expansion may be seen by inclosing the oxygen in any elastic porous envelope, capable of expansion, and through which diffusion can freely take place. It may be observed that unmixed gases (of *unequal* molecular masses, of course) are known to possess a capacity for work, which ceases when the gases become uniformly mixed.

[2] It is conceivable that although the mean velocities or masses might be the same, the mean length of path of the molecules of the two gases might be slightly different. We must therefore either suppose a case where it is the same, or if minute exactness be desired, take it into account.

are an indefinite number of positions these marked molecules (representing the portion of introduced gas) could take up in the vessel, consistent with equilibrium, and there would be (practically) an infinite number of chances against the portion of introduced gas arranging itself as in a vacuum: for to do this, the marked molecules (composing the portion of gas) would require to arrange themselves in such a way that their mean distance is everywhere the same throughout the vessel, a contingency almost infinitely unlikely. What applies to marked molecules applies to chemically different molecules of *equal* mass, or which are *dynamically* similar. Hence it would follow that portions of gas of the same kind, or portions of chemically different gases of equal molecular mass could not be said "to behave to each other as vacua," in regard to *arrangement*. On the other hand, where the gases have unequal molecular masses there is (as we have seen) a forcible dynamical tendency for the gases to diffuse themselves symmetrically through each other, so that each gas behaves to the other as a vacuum, each gas becoming uniformly diffused through the vessel, as if it existed alone in a vacuum. The successive introduction into a vessel of portions of gas of the same kind (or of portions of chemically different gases of equal molecular mass) may be compared to the introduction into any closed space of successive sets of equal differently coloured perfectly elastic balls (the balls being supposed left in free motion among each other in analogy with the molecules of a gas), when evidently no one arrangement of the different coloured balls in the closed space (at any given instant) could be said to be more probable than another, and it would be extremely unlikely that the sets of coloured balls should "behave to each other as vacua," in the sense of each set diffusing itself symmetrically through the closed space, as it would do in a vacuum. But if the sets of balls were of *unequal* masses [in analogy to gases of unequal molecular masses], then no doubt the different sets would behave to each other as vacua, or each set would forcibly tend to arrange itself according to strict dynamical principles, so as to pervade uniformly the entire closed space, precisely as it would do a vacuum.

S. TOLVER PRESTON

OBSERVATIONS ON THE PHYSICAL GEOGRAPHY AND GEOLOGY OF MADAGASCAR

ALTHOUGH Madagascar is known to be the third largest island in the world, its actual size and extent is not very generally understood. It is easy to see how misconception on this point arises, for in maps the island is usually seen only in connection with Africa, and that great continent is so large that it dwarfs by comparison with itself everything in its near neighbourhood, so that the really large island sheltering under its south-eastern side appears but an inconsiderable appendage to its vast neighbour. If, however, we take a good-sized map of Madagascar, and put by its side the outline, to the same scale, of another country with whose dimensions we are familiar, such, for instance, as England, we begin to realise how important an island it is as regards size, being nearly 1,000 miles long[1] by about 250 in average breadth, so that it is nearly four times as large as England and Wales.

During the last ten years much light has been thrown upon the physical geography of Madagascar, principally through the researches of M. Alfred Grandidier, and the numerous exploratory journeys made in various parts of the country by missionaries and others. Until a very recent period there was no reliable map of the island; a number of mountain ranges were shown in positions where no such geographical features are to be found, and the physical geography was completely misunderstood. But it is now quite clear that instead of a "central mountain chain," as described in most histories and gazetteers, there is *an elevated mountainous region*, which, however, does not occupy the centre of the island, but is more to the east and north, leaving a considerable extent of country to the west, and all beyond the 23rd parallel of south latitude, at a much lower level above the sea. Broadly speaking, therefore, Madagascar consists of two great divisions, viz., (1) an elevated interior region raised from 3,000 to 5,000 feet above the sea-level; and (2) a comparatively level country surrounding it, not much exceeding 400 or 500 feet in elevation, and most extensive in the west and south.

The elevated region is largely composed of primary and crystalline rocks. Lines of hills traverse it in all directions, but they do not rise to a very great height, the highest points in the country, the peaks of the Ankàratra group of mountains, being a little under 9,000 feet above the sea-level. A very large extent of this portion of Madagascar is covered with bright red clay, through which the granite and basaltic rocks protrude. But there are also extensive rice-plains, especially near the capital cities of the two chief provinces, where there is a rich black alluvial soil; and it can hardly be doubted that some at least of these plains, from their perfect level, out of which the red clay hills rise like islands, have formerly been the beds of extensive lakes, subsequently drained, possibly by slight changes in the level through subterranean action.

A good deal of this portion of Madagascar is bare and somewhat dreary-looking country. The long rolling moor-like hills are only covered with a coarse grass, which becomes very brown and dry towards the close of the seven months' rainless season; but the hollows and river-valleys are often filled with a luxuriant tropical vegetation, and, wherever there is population, with the bright green of the rice-fields. There is, nevertheless, an element of grandeur in the landscape, from the great extent of country visible from many points in the clear, pure atmosphere, which renders very distant objects wonderfully sharp and distinct. And many portions of the central region possess still greater claims to admiration from its picturesque mountain scenery.

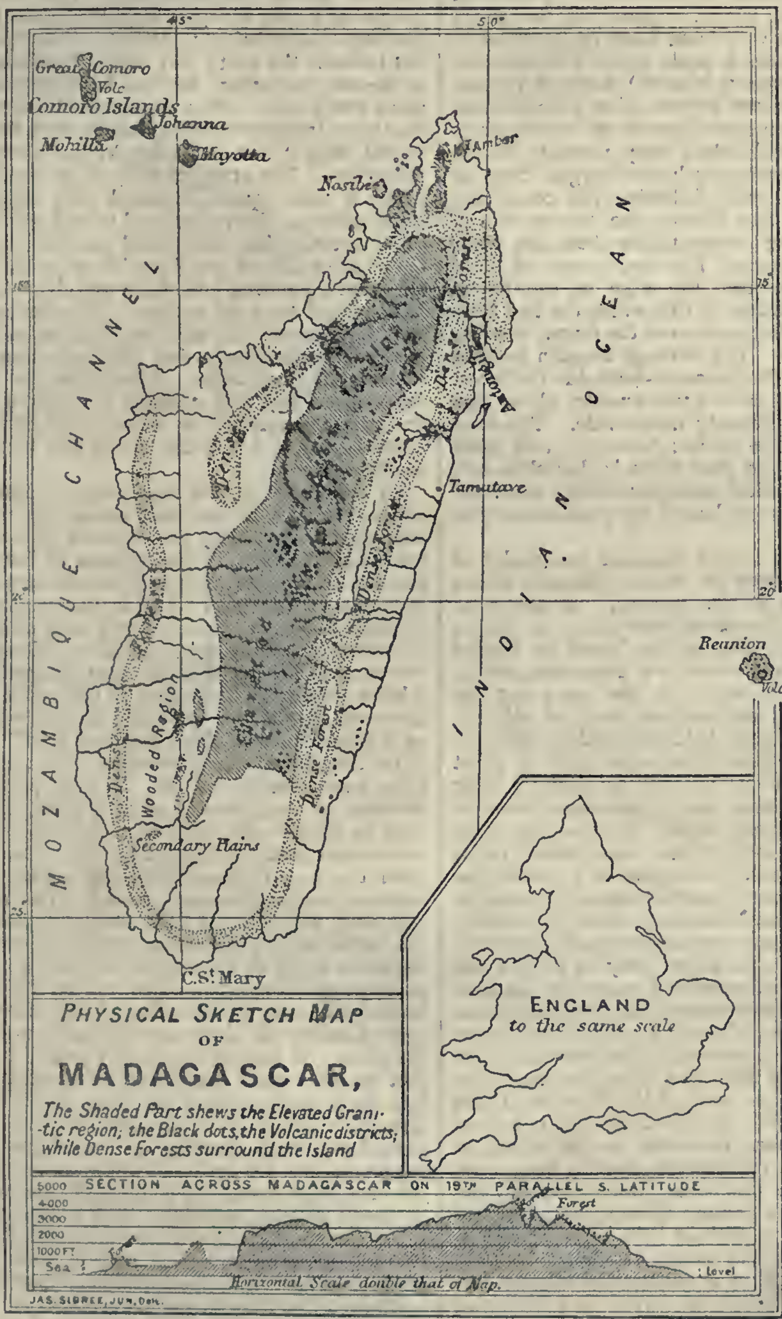
In the southern Bétsiléo country, the grand and varied forms of the mountains filled me with an exultant kind of delight. To the south was a crowd of mountain-tops, peak beyond peak, with the greatest variety of outline: one had the appearance of a colossal truncated spire, another had a jagged saw-like ridge, another was like a pyramid with successive steps, and another an enormous dome. Their summits were never long free from clouds, and many of the peaks must be at least 3,000 feet above the plain.

Sections taken by the aneroid across this elevated region from east to west at the latitude of the capital show that it has a depression in the centre, the edges on either side being considerably higher than the country between them. At some points this height of 4,000 to 5,000 feet is gained by a series of steps from the maritime plains, each range of hills rising higher and higher, while at other points it descends almost at one steep slope for nearly 3,000 feet. The water-shed is not in the centre of the island, but is much nearer the eastern side. Through the eastern wall many of the rivers cut their way by magnificent gorges, amidst dense forest, finding their way to the sea by a succession of rapids and cataracts, and occasionally by stupendous falls, as in the case of the Màtitànana river, which descends at one plunge 500 or 600 feet. Some of the western rivers, also, are said to form grand waterfalls, particularly that of the Mania, whose sound is reported to be heard at a distance of two days' journey, *i.e.*, about forty to fifty miles.

The lower region of Madagascar consists of extensive plains only a few hundred feet above the sea-level, but there are at least three prominent chains of hills traversing it from north to south, one of which appears nearly

[1] More exactly, 975 miles.

continuous in a very straight line for above 600 miles. The eastern side of the island is for the greater part of its extent without any bay or inlet, but the north-western side is deeply indented with large bays, into which the chief rivers fall. This part of the coast is bold and mountainous, and some of the finest scenery in Madagascar is to be found here, as the northern extremity of the volcanic region forms several very grand mountains, particularly the one called Amber or Ambòhitra. This is said to be about 6,000 feet high, and from its isolated position in the low country surrounding it, is a remarkably majestic hill as seen from every direction, as well as from far out to sea.[1] It has three summits, and its sides are clothed with impenetrable woods.



South-west of this mountain is a remarkable rock-fortress of the tribe inhabiting this portion of the country, who are called Antankàrana, that is, "the people of the rocks." It is an enormous, lofty, and precipitous rock, having an elevation of nearly 1,000 feet, and covering an area of about eight square miles. Its sides are so steep that they cannot be climbed unless artificial means are used, and it is thickly wooded wherever trees can possibly grow. The only entrance into the interior of the rock, which is full of caves, is by means of a subterranean passage, a portion of which is extremely narrow, allowing only a single person to pass along it at a time, and has on each side of it deep water.

The other principal group of mountains in Madagascar

[1] According to a French engineer's estimate, it considerably exceeds the above given altitude, being, so he says, 2,700 metres high.

is the great mass of elevated peaks called Ankàratra, in the central province. This has hardly the grand appearance of Mount Amber (although it considerably exceeds the latter in absolute height), since it rises from the elevated region of Imérina, which is at the capital about 4,000 feet above the sea-level. Ankàratra is nevertheless a noble group of hills, and is the most conspicuous feature of the landscape over a considerable portion of the central regions of the island. There are five or six principal summits, which vary from 8,000 to 9,000 feet in height, the most lofty one, a peak called Tsiàfajàvona ("that which the mists cannot climb"), being 8,950 feet above the sea-level, and is the highest point in the island.

Another interesting physical feature of Madagascar, which has only been made clear very recently, is the existence of an almost continuous belt of virgin forest all round the island, and generally following the coast-line. This forest-belt divides into two on the eastern side of the country, leaving a long narrow valley about 250 miles long between the two lines. The uppermost of these clothes the slopes which form the edge of the upper plateau of the island. North of this valley the two lines unite, and here is the widest portion of the forest, it being about forty miles across. The average breadth is from fifteen to twenty miles. On the north-west side the forest is not continuous, but the extremities overlap about 100 miles, leaving an opening seventy miles wide. The total length of this forest must be about 2,300 miles, and much of this is yet unexplored, so that there is doubtless still much of interest in botanical science awaiting research. Besides the forest-belt a good deal of the plain country to the west is well wooded.

A third fact of interest in the physical geography of Madagascar is the evidence of recent volcanic action throughout a great part of the country. It has been known for several years that there were signs of this on the north-west coast, and that in the island of Nòsibé and the adjacent mainland there are numerous extinct craters and much igneous rock. A few years ago the Rev. T. Campbell pointed out evident traces of volcanic agency in the district near the Ankàratra hills. He says: "It seemed as if the whole place were once a great smeltery, from the enormous number of clinkers lying about. There are altogether five mountains all near to each other, which have been active volcanoes at some remote period; each has one of its sides melted down and the inside hollowed out. The flow of lava looks as if it had been some immense reservoir bursting its banks, and the water dashing and foaming through, bearing everything away with it, or covering the plain beneath."

In a journey I took to the Lake Itàsy in 1866, I was struck with the number of truncated cones in the hills surrounding the lake. But extensive journeys made more recently in various directions have revealed the existence of a very widespread and powerful subterraneous action, probably extending almost unbroken from the south-east to the north-west and extreme north of Madagascar. There seems reason to suspect that this volcanic belt is part of a line which has its eastern extremity in the island of Réunion, where there is a volcano still showing occasional signs of activity; while the other (north-western) extremity passes through the Comoro Group (the islands of which consist of grand masses of lofty volcanic mountains), and terminates in the island of Great Comoro, where also, as in Réunion, is a still active volcano. It would seem as if the subterranean forces had expended their energy in the intermediate space, for there is no active volcano in Madagascar, while at each end of the line their presence is still occasionally felt. There are, however, signs of not altogether extinct forces in Madagascar in the slight earthquake-shocks which are felt almost every year, and in the hot springs of various kinds which occur in many parts of the country.

A large number of extinct volcanoes are found west of Lake Itàsy. These are thus described by Dr. Mullens :—"When we ascended the lofty hill overhanging the western end of the lake, crater after crater met our astonished gaze. There were forty in all, of which we were sure; we think there were others beyond to the north." "Fifty miles further south we came on the volcanoes again. We climbed a lofty rounded hill called Ivòko, and then found that we were on the crater wall. The inner hollow was a quarter of a mile wide, the height of the wall above the level country outside being 1,100 feet. Two lava streams went out towards the south and west; three small craters were at the foot, and others, large and conspicuous, were around us on every side. Close by, another huge crater, Iatsìfitra, had its opening towards the north, and the lava that had issued from it was fresh, black, and sharp, as if broken yesterday. But stranger still, at its eastern side was a plain, a mile square, covered with heaps of lava, like stone cottages, fortresses, and ruined palaces. I counted thirty greater piles, and noted numberless smaller ones; it was clear that at one time the entire plain had been on fire, that a hundred jets of fire and flame and molten lava had spurted from its surface. The heaps were now old and moss-grown, but we were informed of a vague tradition among the people that their ancestors had seen these flames bursting forth. Altogether, in that important journey, we saw and counted a hundred extinct craters, extending over an arc of ninety miles, not reckoning the central mass of Ankàratra, round one side of which that arc bends."[1]

In a journey to the south-east of Madagascar I discovered traces of volcanic action in many places; in some parts shown by the deposits of rolled pebbles of lava, and in others by the streams of lava rock running into the sea and forming reefs which were gradually being broken up by the surf. And in the very opposite part of the island, on the extreme north-west coast opposite the Minnow group of islets, Bishop Kestell-Cornish observes :—"This coast is the most distinctly volcanic that I have seen in Madagascar; at one point the lava must have run down to be quenched in the sea, and it looked as if this had taken place only last year."

In the Antsihànaka province also the same plutonic agency is distinctly visible. A great part of this region consists of an immense marshy plain, about forty miles long by twenty wide, with the lake Alaotra at its north-east corner, and surrounded by hills; and it has evidently been the seat of some powerful subterranean force by which this depression was caused. This is clear from the fact that the lines of hills which are seen on both sides the Antsihànaka plain do not run in the same direction as the main valley or depression of the country, but cut it at an angle of about 45°. Many of the ridges seem to be broken off more or less abruptly by the level ground for several miles, and then are continued on the other side of the plain. It seemed impossible to avoid the conclusion that by some great convulsion a vast rent and depression had been made across the lines of hills in a diagonal direction; while the water-worn remains of some of these toward the south, forming a line of low detached hills, suggested that the action of water, either as an arm of the sea or a great river, had completed what was commenced by more violent agencies. The evidence of former volcanic action in the presence of extinct craters and lava streams to the west, north, and north-east of the plain, gives considerable support to this supposition.

About a hundred miles north of the Antsihànaka province there seem to be further traces of the same agency. The Rev. J. A. Houlder thus describes a remarkable valley called Màndritsàra, which, until he saw it in 1876, was unknown to Europeans even by name, and not marked upon any map:—"It is a great basin, or rather a mighty elongated pit, sunk deep down among the surrounding heights. It is about thirty miles long and

[1] *Proc.* Roy. Geogr. Soc., January 25, 1875, pp. 187, 188.

nearly 2,000 feet below the level of the country east and west of it. Dante would have imagined it, not a 'circle' certainly, but a remnant of some region of the horrible pit itself, which for a wise and gracious purpose had been gently touched by the cooling breath of heaven. There had evidently been a great commotion going on there in the ages gone by; for all the long valley was dotted with rounded hills, giving it the look of boiling water or bubbling pitch, which by some strange process had suddenly become congealed."

It will therefore be seen that igneous agency has been a powerful factor in shaping the physical geography of many portions of Madagascar; in few places could that agency have been present in a grander scale than in the volcanic region of which Madagascar is the centre, and the Comoro and Mascarene groups the extreme points in either direction. An attempt has been made in the accompanying sketch-map to show the prominent features of the physical geography of the island already noted. Probably closer examination would show that the detached groups of extinct craters are all connected by intermediate links, so as to form a continuous line of igneous disturbance from the extreme northern point of Madagascar to at least as far south as the 23rd parallel; and from the appearance of a line of hills seen at a distance south of this latitude, I am strongly inclined to believe that there has been subterranean agency at work even beyond the upper granitic plateaux, but no examination has yet been made of this southernmost region.

With regard to the geology of Madagascar, but little is at present known with any exactness, for no competent geologist has yet made a systematic exploration of the country. There are, however, a few facts of a general character which have been noted by various observers, and these may be here collected together as a slight contribution to a knowledge of this subject pending a more complete and scientific treatment of it.

As already mentioned, the elevated region which forms so large a part of the central, northern, and eastern portions of the island is largely composed of primary and igneous rocks. Granite, gneiss, mica schist, and basalt are present almost all through this high region, and generally form the loftiest points in the country. In a single hill there is often a considerable variety of rock both in colour and texture: granite of various shades of grey, red, and rose-colour, with the constituent parts both fine and coarse. Veins of quartz, running both through these and the clays by which they are overlaid, are often met with, and very fine specimens of rock crystal are frequently found. A hard whitish stone, which has some resemblance to the Yorkshire stone called Bramley Fall, is used in Antanànarìvo for public buildings, as well as for the native tombs.

The lower hills, as well as the high moors, are usually composed of a bright red clay, but below the surface this often seems to pass into a light pink or white earth resembling kaolin or china clay. This frequent change of colour would lead one to infer that atmospheric influences have something to do with the difference between the surface clay and that exposed in the numerous precipitous clefts which the rains excavate on the hill-sides. In many places the material found amongst the rock seems exactly like granite in its constituent parts, but without the cementing elements, so that it can be cut quite easily by a spade. The red clay is sometimes varied by a light brown clay on the hills, while the plains and valleys are filled with rich alluvial clays, blue and black in colour. In all these clays there is an apparently total absence of all organic remains, either animal or vegetable, so that it is not an easy task to determine their geological age, and there is little sign of stratification, although I have detected some appearance of this in the rocks, with tilting of the strata.

In this elevated region there seem to be few, if any, sedimentary rocks of a more recent age than the primary ones which are so prominent a feature of it. A soft dark red stone is found in some places, but this appears to be only a hardened clay. Columnar basalt has been noticed in two or three places, as well as extensive beds of volcanic ash, decomposed lava, scoria, and lava rock of all varieties of hardness, in some of which crystals of olivine are found in abundance.

At one point, however, in the upper region of the island a limestone deposit occurs. This is at Sìrabé, to the south-west of the Ankàratra mountains, and from the pits dug here most of the lime used for building in the central province is procured. It has not yet been examined by any one with competent scientific knowledge, but it appears to be a sulphate of lime, and is probably only a local deposit and not a stratified rock, and most likely is connected with the subterranean action so visible all around the district.

Clay slate is met with in the southern part of this elevated region; and in the Bétsiléo country a valuable slate, suitable both for building and for writing upon, is found, although it has not yet been worked to any extent. According to some accounts, greywacke or whinstone, silex, and chert with chalcedony, are also met with in the southern highlands.

From certain of the facts above given, as well as from other considerations, it appears highly probable that the extensive elevated region of Madagascar is very ancient land, and has most likely remained for many ages above the waters of the Indian Ocean; otherwise, some trace of marine deposits would surely be found in some portion of this great extent of country. I may, however, here note the fact that there are in some places such rounded boulder-like masses of blue basalt rock, sometimes on the surface and sometimes partially embedded in the soil, that did these occur in the temperate zone, one would certainly ascribe them to glacial action; but the point requires fuller investigation, and possibly some other solution may be given to the rather puzzling inquiry suggested. But in travelling to the north-west coast, as we got near the sea-level, we met with boulders composed of rock which certainly is not found *in situ* anywhere near the spot where these boulders occur, but has come from far away in the interior.

With regard to the lower region of Madagascar—the extensive plains to the west and south of the island, as well as the narrower extent of country on the east coast—we have a little more definite information as to the geology of some portions of it. This division of the country is only as many *hundreds* of feet above the sea as the granitic region is *thousands* of feet; and there we find not only deposits of the later Tertiary epochs, containing fossils of animals but recently extinct, but also fossils of the Secondary age. This fact was first pointed out by M. Grandidier, who, in speaking of the south and west portions of the country, says: "*Nerinea* and other characteristic fossils of the Jurassic formation which I have there collected prove the existence of Secondary strata, which cover a vast extent of this island" (*Bull. de la Soc. de Géog.*, août, 1871, p. 88). In a later number of the same publication (avril, 1872) he also speaks of an extensive "terrain nummulitique parfaitement charactérisé par des *Neritina schmideliana*, et pétri de foraminifères appartenant aux genres *Alveolina*, *Orbitoïdes*, *Triloculina*, &c." This is confirmed by the fossils discovered in the south-west of Madagascar, in the upper part of the valley of the St. Augustine river, by the Rev. J. Richardson in 1877. These occur in vast numbers, and from a drawing he gives appear to belong to the Neocomian formation, and are species of the genera *Ammonites*, *Terebratula*, *Nerinea* or *Turritella*, *Einoceramus*, and *Rhynconella*, together with an *Echinoderm*.

It is evident also that there are deposits of a much later date than the above, for in the south-west of Mada-

gascar M. Grandidier discovered the fossil remains of a hippopotamus (a pachyderm not now living in the island), of gigantic tortoises (which are now only found in the little island of Aldebra to the north of Madagascar), and of the probably very recently extinct struthious bird, the *Æpyornis maximus*, whose egg ($12\frac{1}{4}$ in. $\times 9\frac{1}{4}$ in.) so far exceeds that of any other known bird. It seems highly probable, therefore, that a systematic examination of these less elevated portions of Madagascar would reveal the existence of much that is interesting both in palæontology and geology, and so light would be thrown upon many problems connected with the anomalous animal life of the country and of the neighbouring islands in the Indian Ocean. It is evident that these maritime plains were under water during portions at least of the Secondary period, at which epoch the high granitic region alone formed the Island of Madagascar, then a country probably only a third of its present extent.

Dr. Auguste Vinson speaks of seeing yellow sandstone on the eastern coast, and he also describes the plain between the two eastern lines of forest as being composed of beds of sedimentary formations, "rich in fossil remains." Unfortunately he gives no particulars as to these alleged extinct organisms, so we are still in the dark as to the geological age of these formations. In sailing down the river Bétsibòka to the north-west coast, I noticed at one point that for a considerable distance the river bank was formed by layers of yellowish sandstone closely resembling a low wall of masonry. Some of the courses appeared much weathered, while others had a smooth face as if of much harder materials.

From the account given by an intelligent native of some rocks in the western part of Madagascar, and a little to the south of the centre, a conglomerate seems to be found there, for he describes hard rocks of great size as being filled as thickly as possible with rolled pebbles of all dimensions and shapes. He also mentions that near the sea he found a hard black stone which rang like iron, and was full of shells in good preservation and appearance. Unfortunately he too brought no specimens for examination.

A little more information as to the geology of Madagascar is found in papers contributed to scientific periodicals in England and France several years ago. The earliest of these is by the late Dr. Buckland, who, in a "Notice on the Geological Structure of a Part of the Island of Madagascar" [1] (Port Louquez, near the northern extremity), describes a sandstone without fossils, which he compares to the New Red Sandstone, and in which are intercalated trap-rocks similar to those of Antrim in Ireland.

As to the north-west side of Madagascar, in the *Annales des Mines* (1854, 5me série, t. vi. pp. 570-576) there is a paper on the discovery of beds of lignite both in the island of Nòsibé and at two points on the north-west coast. In the opinion of the officers who made the exploration the beds of this combustible are more ancient than the Tertiary formation. It is contained in layers of sandstone and clay schists, is fibrous, and shining, and burns readily with a long and white flame, leaving little ash. If beds of this lignite should be discovered in greater thickness it will therefore be valuable both as steam coal and for use in the industrial arts.

In the same French publication of a little later date (5me série, t. viii., 1856) there is an "Essai sur la Géologie de Nòsibé," in which the soil of that island is described as consisting of three different groups of strata:—(1) granitic rock, gneiss, mica-schist, slaty-schist, and plastic clay; (2) red and yellow sandstones, traversed by veins of gneiss and quartz; while (3) is essentially volcanic, consisting of basaltic and trap lavas, overlaid in some places by beds of sandy material, tuffs, and volcanic *rappilis*. The essay is accompanied by a complete geological map.

[1] *Trans.* Geol. Soc. London, vol. v. p. 478.

Since the date of this last paper some further attention has been paid to this part of the country in connection with the French Company proposed by M. Lambert,[1] but hardly anything more has been done towards a scientific examination of other portions of Madagascar except a slight notice of the peninsula inclosing Antongil Bay,[2] although probably M. Grandidier will have some fresh information in his great work now in progress.

It may be here observed that a reef barrier of coral extends for at least 350 miles along the east coast, varying in its distance from the land from a quarter of a mile to three or four miles; while fringing reefs surround the northern end of the island, extending for 400 miles down its eastern side, and are also found on the south-west coast.

With regard to minerals, Madagascar is tolerably rich in some of the most useful metals. Iron is found in great abundance in Imérina, sometimes almost in a pure state. In some of the hills it is so plentiful that it is difficult to get a bearing with the compass, from the deflection caused by the iron in the ground. Copper, lead, and silver have also been discovered, and from the geological structure of the country it is highly probable that gold would be found in some of the ravines of the granitic highlands; but as it is at present a serious offence against the native laws to search for the precious metals, hardly anything has been done in this direction. Rock-salt is found near the coast, and nitre is also met with. Iron pyrites, from which sulphur is extracted, is also found in abundance; in the northern part of the island antimony seems to be plentiful, and oxide of manganese has been found about fifty miles south of the capital. A substance resembling plumbago exists in great abundance, and is used by the Malagasy to colour and glaze some of their articles of pottery. A considerable variety of ochres and coloured earths are met with, and are used not only for colouring the native houses, but also in dyeing some of the woven cloths made by the people.

In conclusion, it may be remarked that there is a vast extent of country on the coast-plains where the soil is most fertile, but which is only thinly peopled, or has no population at all. Many parts of the island which separate the territory of one tribe from another are well watered and wooded, and seem to invite occupation. Madagascar could well sustain a population from ten to twenty times its present amount, for hardly any portion of it is rainless or desert, except a small section of the extreme south-western coast. Surrounded by the ocean it enjoys an abundant rainfall, so that the droughts which constantly afflict large portions of Southern Africa never occur in Madagascar, while its insular position gives it a more equable climate, freer from extremes of temperature, than is enjoyed in most tropical countries.

JAMES SIBREE, Jun.

NOTES

THE first zoological station established in Scotland was opened the other day at Cowie, near Stonehaven. The work, which is more directly in connection with the natural history class of the Aberdeen University, will be carried on in a small wooden house which was erected in the beginning of last week on flat ground, a few yards to the north of Cowie, and close to the sea-shore. The building was constructed in sections, special provision being made for ventilation. It consists of two apartments, the lesser of which is to be fitted up as a library and office, while the main room will be devoted to reception of the proceeds of the dredging, trawling, and other expeditions. The latter department contains the dredging and trawling apparatus, a number of microscopes, with chemical and other appliances

[1] See *Annales des Mines*, 6me série, t. x. pp. 277-319.
[2] *Bull. de la Soc. de Géog.*, Sept. et Oct., 1867.

necessary. Two boats are at the disposal of students—a large yawl and a small boat, kindly lent by Major Innes of Raenoir, who has also given the use of his drill-hall as a store. A select party assembled at luncheon, after which Mr. G. J. Romanes, in a brief and happy address, formally declared the station open. The total sum now raised is 350*l.*, but this is not enough, and we regret that the appeal made through our columns and elsewhere, has not been so successful as it should have been. This, we believe, is more due to want of thought than illiberality, and we trust that the work at this the first genuine zoological station in the kingdom, will not be crippled from want of sufficient funds. Mr. Romanes will be happy to receive further subscriptions.

ON Friday, in the House of Commons, Mr. Shaw-Lefevre asked what arrangements had been made as to the management of the Natural History Collection about to be removed to South Kensington? He hoped that advantage would be taken of this opportunity to make some change, so that the management of that collection might be entirely different from the management of the other collections of the museum. In reply, Mr. Walpole said that the recommendations made by the Royal Commission were communicated to the Treasury in February last, and were then transmitted to the trustees of the museum. The trustees had carefully considered those recommendations and had sent in a scheme to the Treasury, and the matter was now in the Treasury's hands. The views of those who took a particular interest in scientific matters and in the advancement of science had been taken into consideration, and he thought he might say the future management of the museum would give complete satisfaction, not only to them, but to the public generally.

DR. J. FR. BRANDT, the veteran Russian naturalist of St. Petersburg, whose works were referred to in last week's Notes, died on the 7th ult., at the age of seventy-seven. Dr. Brandt has been for many years director of the Imperial Museum of Zoology in the Russian capital, and is author of many important memoirs in the *Transactions* of the Imperial Academy of Sciences of St. Petersburg.

THE *Times* announces the death of Prof. Lamont, a Scotchman by birth, and director of the Munich Observatory. Prof. Lamont, who was seventy-four years of age, and had been employed at the Munich Observatory since 1835, may almost be called the father of modern terrestrial magnetism.

THE death is announced of Herr Joseph Haardt von Hartenthurm, one of the most eminent of German cartographers. He died at Vienna on July 28, at the early age of thirty-nine.

THE proceedings of the first Austrian Anthropological meeting began on July 28, the assembly being exceedingly numerous. Prof. von Hochstetter was the president, and spoke on ambulant meetings for the purpose of common work. Herr Deschmann, of Laibach, read a paper on the latest discoveries in the heathen hill tombs of St. Margarethen. Prof. Gurlitt, of Graz, spoke on clay vases, and Prof. Alfons Müllner on the method of beginning practical work in anthropology. A paper was then read on local geographical and personal names in Carniola, by Dr. Arnold von Luschin. On the 29th Count Wurmbrand and Herr Szombathy delivered lectures on skull measuring and investigations relating to the colours of hair, skin, and eyes. Herr Scheyer spoke on ancient sepulchres, and Herr Obermüller on prehistoric times. In the afternoon the meeting visited the lake-dwellings in the Moorgrund.

AT the celebration of the 100th anniversary of the foundation of the "Naturforschende Gesellschaft" at Halle on July 30 last, Prof. Knoblauch welcomed the guests in an able address. Afterwards the secretary of the Society, Dr. Marchand, gave a historical retrospect of the Society's activity, and then followed a "festival" address by Prof. Kraus and the reading of a letter from Dr. Naegeli, of Munich.

A MODEL of Mr. George Fawcus's gun-carriage slide (referred to in NATURE, vol. xx. p. 337) may be seen at the Royal United Service Institution.

THE *Tokio Times* of May 10 reports a meeting of the Biological Society of the Tokio dai Gaku, on Sunday, May 4. Prof. Yatabe made a communication on the flora of the Bonin Islands. He showed how seeds could be transported thither by means of currents, and called attention to the various currents affecting the fauna and flora of the dependency. He then described the general character of the flora, and pointed out the differences between the plants of the islands and Japan proper. He also called attention to the similarities existing between those of the Bonins and Southern China and India. Mr. I. Iijima communicated some facts regarding the habits of a species of pteropus, a large winged bat from the Bonin Islands, a living male specimen of which was exhibited to the Society. After briefly stating its relations to the mammals, and that the individuals of this group were frugivorous, he stated that there were about forty species known, distributed among the islands of the Pacific. The Bonin Island pteropus subsists chiefly on the banana, frequenting the trees during the daytime, and at night flitting in the air in considerable numbers. The features closely resemble those of the fox, and hence the name of flying-fox generally given them. The fur is long and black, with white hairs intermixed. A few hairs taken from the specimen and others from a Sumatra species were shown under the microscope, and their peculiarities explained. The pteropus constantly hangs from the roost head downward; and when about to sleep hangs by one leg, spreads its wings, and then wraps them closely about the breast, hiding its head beneath the membranous folds. The specimen had been fed almost exclusively on sweet potato, though it would eat boiled peas and rice, and orange if it was juicy. If a big piece of sweet potato is given it, the fragment is grasped by one of the hind legs, and not having an opposable thumb, it is held firmly against the breast. Reaching up the head, the bat tears away a large mouthful and then chews it a long time, making a smacking sound in the act, and at each movement of the jaws thrusts out its lanceolate tongue. The fibre of the potato and pulp of the fruit is invariably ejected from the mouth, and just before doing this, one or two vigorous sucks are heard, as if the animal was drawing out the remaining juice. This performance is accompanied by a singular jerk of the head. In the act of chewing, the morsel is changed from one side of the mouth to the other. When its appetite is fully satisfied it begins to scratch its body with its hind leg. The long tongue also comes into service to cleanse the fur. It is a curious sight to see the long nail on the thumb used as a toothpick. The toes are also employed for a similar purpose. Prof. Yatabe remarked that the banana was not indigenous to the Bonins, but had been introduced, and the pteropus had acquired a taste for it.

ARAGO having been born at Estagel, a small country place in the department of the Pyrenées Orientales, the citizens of Perpignan, the head town of this district, have decided to erect a statue to him by public subscription. The inauguration will take place on September 21 next, and will be celebrated by a three days' *fête*. We are informed that an address will be delivered by M. Paul Bert, the physiologist, and influential member of the Chamber of Deputies. It is strange that no astronomer or physicist has been selected for this great occasion.

THE French Parliament voted before the vacation a law obliging landed proprietors to protect their vines against the invasion of the Phylloxera. The *Journal Officiel* publishes a report signed by M. Teissoniere, member of the Council of the Society

of French Agriculturists, and vice-president of the Chamber of Commerce of Paris, showing the efficacy of sulpho-carbonate for destroying that pest. The experiment was made on 464,557 plants, covering a surface of 110 hectares, or 272 acres. A quantity of about 35 tons of sulpho-carbonate was employed with 10,000 cubic metres of water. The total expense was about 4*l.* per acre. This sum will be reduced very shortly in a large proportion by a diminution of the sulpho-carbonate, which actually costs 2*l.* per cwt., and will be sold at 1*l.* when the method has been adopted on a large scale. The plants were unhurt, and the vegetation was found to be luxuriant. Insects injurious to grapes were destroyed at the same time.

ON the occasion of the inauguration of M. Thiers' statue an aëronautical ascent was made at Nancy on August 4. The wind was blowing from the west with a velocity of 16½ kilometres an hour, and no variation in the direction was perceptible from the ground to 800 metres. The altitude of the balloon was taken by officers from Mazléville, with a theodolite, and signals were exchanged with the ground during the ascent. The signals were given by the aëronauts with a flag, and by officers with a reflecting mirror placed in the end of a tube, and mounted as a telescope. The officers directed the rays of the sun on the balloon, and intercepted rays with a key in order to use the Morse alphabet. The distance of Mazléville from the balloon was more than six kilometres, and the signals could be seen at a much greater distance. This shows that in a besieged town a passing balloon could be used for giving orders to, or receiving news from friendly forces. The system of communication has been invented by one of the officers of the garrison. M. W. de Fonvielle was in the car.

IN 1789 the Royal Library of Paris contained 800,000 volumes and objects of every description. In 1859 the number averaged 1,200,000. During the last twenty years the increase has been more sensible, and the actual number is estimated at 2,000,000. The mean annual increase from legal deposits alone is 20,000. Out of these 2,000,000 about 450,000 are devoted to French history, 200,000 to theology, 90,000 to science and philosophy, 60,000 to natural history, and 120,000 to English history. The greater part of French and English historical and medical works are arranged in printed systematic catalogues placed in the hands of the public. In less than ten years the whole of the catalogues will be printed.

THE Trustees of the South African Museum at Cape Town issue a very satisfactory report for 1878. Several important improvements have been made in the building, valuable additions, especially of insects, have been made, and the collection has been inspected by a large number of South African and foreign naturalists.

A BRIGHT meteor was observed in many places in Saxony and the adjacent Voigtland, during the night of July 26–27. An observer at Droeda (a village in the south-west corner of the kingdom) reports: "At 12.45 the nocturnal darkness was suddenly interrupted by an illumination of the whole firmament, which nearly reached daylight in intensity, and which lasted for three seconds. A beautifully bright blue fire-ball was slowly moving in the heavens from south to north. At Plauen the fall of the meteor was observed, and at Greiz even two fire-balls were seen." Corresponding news reaches us from Leipzig, Dresden, Zwickau, Wiedersberg, &c.

MR. MORRIS's report on the Ceylon coffee-leaf disease, to which we have before referred, urges the necessity of uprooting trees which are very seriously affected, and of treating the remainder with a compound of sulphur and lime. Grass, it is urged, should not be left near the trees, and all diseased leaves should be burnt. Before leaving Ceylon for Jamaica, Mr. Morris was to deliver an address to the Chamber of Commerce on the all-important subject.

THE *Times* Berlin correspondent states that Dr. Schliemann, after having spent a month's holiday at Kissingen, has gone to pass a few days at his home in Mecklenburg, after which he will proceed to London to superintend the publication of his new work on Troy, embodying all his most recent researches, to which Prof. Virchow will contribute the preface.

AN extremely satisfactory report for 1878 is issued by the Manchester Scientific Students' Association. It contains several interesting papers, including a short presidential address by Prof. Williamson, and instructive accounts of the numerous excursions of the Society. A satisfactory report for 1878-9 has also been issued by the Leicester Literary and Philosophical Society, and we are glad to see, from the seventh report of the Leicester Town Museum, that that institute is steadily improving. Mr. Octavius Stone's New Guinea Birds are being arranged in their new cases by Mr. Montague Brown, and will shortly be ready for exhibition.

THE Peking correspondent of the *North China Herald* states that a college will shortly be opened there for the training of young diplomats, and it is understood that it will be under the direction of a former professor in the Tungwên College, aided by competent assistants.

SOME time ago the *Japan Gazette* stated that the Government were engaged in surveying a line of railway from the coal mines at Horouchi, in the island of Yezo, to Koishigari, a town on the chief branch of the River Ishigari. The survey has now been completed, but the original plan has been altered materially. It appears that the country for some distance along the proposed route is low and subject to occasional inundations from the overflowing of the river. One of these recently occurred, and showed the difficulties of the proposed route. It has, therefore, been determined to make a shorter line to the village of Horouchi, on another branch of the Ishigari, which is navigable for flat-bottomed vessels. The specimens taken from these coal-mines to Yedo are said to be very fine, and as the mines are to be worked on the most approved system, they are expected to prove a great national benefit.

SOME valuable kerosene springs are stated to have been discovered in Uzen and Ugo, two Japanese provinces lying to the north of Yedo.

A JAPAN paper states that the new arsenal and dockyard to be founded at Mihara for the Japanese navy will be very complete and magnificent. Dry and wet docks are to be constructed fit for the largest war-ships; and there will be iron sheds, in which ironclads and wooden war-vessels may be built without hindrance from the weather, as well as foundries, engine-shops, rolling mills, stores, &c. The expense of these works, it is expected, will be enormous, especially as there are also to be barracks and fortifications for their protection.

THE additions to the Zoological Society's Gardens during the past week include a Rude Fox (*Canis rudis*) from Demerara, presented by Mr. G. H. Hawtayne, C.M.Z.S.; a Grey Flying Squirrel (*Sciuropterus fimbriatus*) from North India, presented by Mrs. Louisa Edwards; a White-whiskered Swine (*Sus leucomystax*) from China, presented by Mr. Theodore Hance, C.M.Z.S.; a Black-faced Ibis (*Geronticus melanopis*) from Chili, presented by Mr. C. H. Whaley; three North American Turkeys (*Meleagris gallopavo*) from North America, presented by Mr. R. Wynne Roberts; three Common Kestrels (*Tinnunculus alaudarius*), European, presented by the Rev. J. E. Campbell Colquhoun; two Vociferous Sea Eagles (*Haliaëtus vocifer*) from East Africa, presented by Dr. J. Kirk, C.M.Z.S.;

a Lanner Falcon (*Falco lanarius*), East European, presented by Lord Lilford, F.Z.S.; a Wood Owl (*Syrnium aluco*), European, presented by Capt. F. Lloyd; two Vulturine Guinea Fowls (*Numida vulturina*), four Elliot's Guinea Fowls (*Numida ellioti*), three Mitred Guinea Fowls (*Numida mitrata*) from East Africa, deposited; a Pileated Jay (*Cyanocorax pileata*) from South America, two Black Storks (*Ciconia nigra*), European, purchased; a Red-fronted Lemur (*Lemur rufifrons*) from Madagascar, a Tamandua Ant-eater (*Tamandua tetradactyla*) from South America, a Black Hornbill (*Buceros atratus*) from West Africa, four Specious Pigeons (*Columba speciosa*), a Banded Tinamou (*Crypturus noctivagus*) from South America, received in exchange; an Amherst Pheasant (*Thaumalea amherstiæ*), three Fork-tailed Jungle Fowls (*Gallus furcatus*), three Chilian Pintails (*Dafila spinicauda*), seven Brazilian Teal (*Querquedula brasiliensis*), an Australian Wild Duck (*Anas superciliosa*), bred in the Gardens.

ON SPHENOPHYLLUM, ASTEROPHYLLITES, AND CALAMITES[1]

I HAVE just received from Herr D. Stur an abstract of a memoir in which he announces that he has obtained a specimen from the Carboniferous rocks in which he finds twigs of Asterophyllites and Sphenophyllum, forming the branches of the stem of a Calamite, and that the strobili of Bruckmanniæ occur at the ends of such of the branches as support Sphenophylloid leaves. Herr D. Stur appears to regard Sphenophyllum as representing the foliage of the fruiting twigs of the plant, whilst Asterophyllites represents the ordinary vegetative foliage of the same plant.

That this should be true, so far as regards the unity of Asterophyllites and Sphenophyllum is concerned, appears to me to be most probable. As you are aware, I carefully investigated this subject in Part V. of my series of memoirs "On the Organisation of the Fossil Plants of the Coal-Measures." Accepting the conclusions of M. Renault, published in some of his valuable memoirs on the St. Etienne plants, as conclusive so far as Sphenophyllum is concerned, I showed that plants which are undoubtedly examples of Asterophyllites have stems the internal structure of which is identical with that of M. Renault's Sphenophyllums. These facts led me to the inevitable conclusion that the two genera were very closely allied to one another. In my Memoir, Part IX., I described an additional specimen (Fig. 32), which gave further support to my previously expressed opinion, and the further investigations which I then conducted led me unhesitatingly to affirm "that Asterophyllites and Sphenophyllum are genera so closely allied, *that their separate existence finds but little justification in nature*" (*loc. cit.*, p. 334). In fact, it has long appeared to me that, morphologically, the leaflet of Spenophyllum was merely the resultant of the coalescence of two or three leaflets of Asterophyllites.

Herr D. Stur's discovery appears to afford an unanswerable confirmation of these views. His further discovery of Volkmanniæ[2] connected with his plant, which combines Sphenophyllum with Asterophyllites, further sustains a conclusion which I have arrived at in my memoir, Part V., pp. 55–56, viz., "that *Calamostachys* (Volkmannia) *binneyana* has much closer affinities with Asterophyllites than with Calamites" (*loc. cit.*, p. 65).

But Herr Stur further states that the stem from which these Asterophyllitean and Sphenophylloid twigs spring is a Calamites which he names *Calamites sachsii*. Not being acquainted with the plant to which he gives this name, I can form no opinion as to its nature; but I must confess I find it impossible to believe that it can be a Calamite of the common and only type which we find in England. Both my memoirs, Part I. and Part IX., contain a series of illustrations of the structure of our English Calamites, from that of stems that must have been nearly half a metre in diameter down to twigs having only a diameter of ·000837 of a metre, which latter specimens are, I presume, the most minute examples that have been recorded by any observer. Yet all these graduated Calamites have exactly the same typical structure; they possess an ample medulla, which becomes fistular at an early age; this is surrounded by a circle of longitudinal canals, which run from node to node. External to each canal we find a corresponding wedge-shaped mass of radiating vascular laminæ. These wedges are widely separated, in young plants and branches, by large, radial prolongations of the pith—the primary medullary rays of my memoirs—but in older branches these rays diminish in size, so that the wedges become blended together at their broad subcortical portions. These Zylem structures are enclosed within a true Phloem, which is uniformly parenchymatous in its young state, but which becomes differentiated into two or more layers, as the plant grows older; the chief of these layers, so far as size is concerned, being a thick mass of prosenchyma. Now the internal structure of Asterophyllites and Sphenophyllum differs from that of Calamites *in every one of these features*. The youngest twigs, as well as the larger branches of these two genera, are equally devoid of a medulla. The place occupied by that cellular tissue in the *young* Calamite is filled, in equally young twigs of Asterophyllites and Sphenophyllum by an *exclusively vascular* bundle, transverse sections of which exhibit the form of a remarkable triangle with three very concave sides. There are no inter-nodal canals, and the vascular zone, which is largely developed externally to the primary triangular vascular bundle by an exogenous process of growth, is *not* divided into separate wedges by large primary medullary rays. In Calamites each vascular wedge is subdivided into laminæ by numerous, perfectly developed, secondary medullary rays. In Asterophyllites and Sphenophyllum, these rays are of the most rudimentary character, though they exist, as my friend M. Renault has shown, in the shape of groups of cells distributed through the vascular zone.[1]

The bark of the two genera in question is as distinct from that of Calamites as are the medullary and Zylem portions of the respective stems. It consists of two layers which have no counterparts in the Phloem of Calamites. In addition to these details, there is a general triquetrous arrangement in the organisation of Asterophyllites and Sphenophyllum, which has no existence in Calamites. The foliar vascular bundles of the former are only given off from the apex of each of the three prolonged angles of the central triangular bundle of the young twig, whilst no one of the wedges forming the regular Zylem-cylinder of the Calamite has any predominance over the rest.

Such extreme and fundamental differences as these, affecting, as they do, the structure of every layer of tissue from the centre to the periphery of the axis, and at every stage of its growth, make it absolutely impossible that Asterophyllites and Sphenophyllum can be associated with any of the Calamites that are so abundant in our English coal-measures, and with the organisation of which we are now so perfectly acquainted.

That the stem so long, but so improperly, associated with the genus Calamites, viz., the *Calamites verticillatus* of Lindley and Hutton may have been the arborescent stem of these Sphenophylloid plants is as I have shown in my Memoir, Part V., extremely probable. But, I repeat, this stem has no claim whatever to be included amongst the true Calamites.

Such being the conclusions at which I have arrived from the careful study of the inner structure of an enormous number of stems of Calamites and Asterophyllites, and from a comparison of these latter with the facts published in the valuable Memoirs of M. Renault on Sphenophyllum, I shall look forward with great interest to the results of a critical examination of the stem which our fellow-labourer at Vienna has discovered.

W. C. WILLIAMSON

[1] This brief contribution was originally a letter to Prof. Weiss, of Berlin, but it was kindly translated by him, and published in the *Neuen Jahrbuch für Mineralogie, Geologie und Paläontologie*, Jahrgang, 1872, as a communication, with the title of "Sphenophyllum, Asterophyllites, und Calamites, deren Stellung zu einander nach den letzten Beobachtungen." It is only republished now as being necessary to the understanding of Prof. Weiss's interesting communication, which he published along with mine, and which it appears to me desirable to republish for the benefit of English palæo-botanists. I am indebted to my friend Mr. Hartog for its translation into English.

[2] Herr Stur's Bruckmanniæ appear to be that form of spike long designated Volkmanniæ, but now separated as Calamostachys, and of which the *Calamostachys binneyana* is the only British example with the internal organisation of which we are acquainted.

[1] So imperfect is the organisation of these medullary rays, that M. Renault is not prepared to recognise their claim to the title, a point on which I am obliged to differ from him.

Further Remarks to the Preceding Treatise, by E. Weiss, Berlin

Stur's remarkable paper, to which the above communication of Prof. Williamson, the esteemed investigator of Manchester, refers, is the description of a slab on which several branches of Asterophyllites give off, at certain points, lateral twigs with the foliage of *Sphenophyllum dichotomum*, some of which bear terminal spikes of Volkmannia, Stur; at other points he finds

the same Asterophyllites bearing spikes of the type Bruckmannia, Stur, and in such relations that it can only be the offset from a Calamites found lying with it, of which no definition is given, but which has previously been designated *C. sachsii*, Stur. From this Stur draws the following conclusions:—1. Sphenophyllum is a branch of Asterophyllites. (2) Both Sphenophyllum and Asterophyllites are branches of a Calamites. (3) Sphenophyllum is not a distinct botanical genus, but the Macrosporophorous branch of an Asterophyllites—that is of a Calamites. This, if correct, would be one of the most remarkable results in Palæophytology. A Calamites bearing not only twigs, ascribed hitherto to different genera, but to such different fructifications! and besides, we have the incompatibility in the anatomical structure of the stems of Calamites and Sphenophyllum, to which Williamson's remarks are directed. It is not every one that can step so lightly over these difficulties in order to unite the three genera into one. Some grounds, one would think, are still left, not only to indicate, but to compel the separation of these genera, and even to warrant their location in different families, and to call for caution in the interpretation of such facts as the above. To estimate the importance of these facts, we will call attention to the present state of the question.

The widespread genus Calamites, whose structure has been elucidated by Williamson and others, is now almost universally associated with Equisetum in the group Calamariæ, while, as is known, Sphenophyllum has been repeatedly classed with Lycopodiaceæ within the last few years. Williamson insists on the anatomical incompatibility between Calamites and Sphenophyllum (with which he includes Asterophyllites) as brought out by his own microscopical researches; and indeed all previous investigations in botany would protest against the insertion of twigs with the structure of Sphenophyllum on stems or branches, with the structure of Calamites. They possess, in common, only the external characters of the transverse segmentation of the stem, and the conformity of the separate internodes; but this conformity of segmentation is the chief ground for Stur's view, that all such genera as Annularia, Asterophyllites, and now also Sphenophyllum, pass into Calamites. Many stems, such as that bearing *Stachannularia tuberculata* (see my Carboniferous Calamites in *Abhandl. zür geolog. Specialkarte von Preussen*, Band ii. Heft i., Taf. ii. Fig. 1), are Calamites in his eyes, which others do not recognise as such, and he will not allow of any [systematic] severance of a section of the Calamarioid stems from Calamites proper. Hence it is that from Calamites, Stur, most divers things ramify.

In the second point of importance, however, the close conformity of Asterophyllites and Sphenophyllum, Williamson agrees with Stur. According to him, either the two genera have altogether the same anatomical structure, or, at least, there are plants resembling the former having the stem-structure of the latter. Renault, on the contrary, is convinced that some of Williamson's preparations really belong to Sphenophyllum, agreeing with the fragments from Autun and St. Etienne investigated by himself.[1] The twigs which show Calamite structure are referred by Williamson to Calamites, and appear to be those which, without a knowledge of their internal structure, would be placed in Asterophyllites. These would come under Calamocladus of Schimper, whilst Williamson's Asterophyllites appear to be next related to Sphenophyllum.

These two forms agree so closely in the external characters of their sterile parts as to be undistinguishable without microscopic investigation; so that one is inclined to leave them together under the old provisional generic name of Asterophyllites, despite their probable essential difference. That section of Asterophyllites which shows the same stem-structure as Sphenophyllum may be allowed to be closely allied thereto, and, in some cases, even to belong to the same individual as Stur's discovery would indicate. It is possible that in well preserved fossils we may still find some single [external] character, which will distinguish this section of Asterophyllites from those which approach Calamites. It would lie in the decided trimery of the leaves in the verticils of the former (when regularly developed), corresponding with the triangular bundle of the axis, from the angles of which the vessels of the leaf spring. The difference of leaf-form as an absolute character separating Asterophyllites and Sphenophyllum must now be given up.

From the botanist's point of view there is another very important ordinal or generic distinction, to be found in the fructification. Every one must be astonished at Stur's pointing out both Bruckmannia and Volkmannia spikes on his plant. By the former he means Calamarioid spikes with sporangiophores and sporangia between pairs of approximated verticils of Bracts (Calamostachys, Auct.). By the latter, spikes with sporangiophores and the sporangia axillary (Palæostachya, Weiss.) Whether these two arrangements are really present here is not yet clearly shown; at least, in answer to my inquiries, Stur gives no definite information on that point, but refers to the forthcoming fuller memoir which he promises. Hence it is still an open question whether the arrangement is not that hitherto alone recognised as that of Sphenophyllum—that is, sporangia without sporangiophores, sessile in or near the axils of the leaves. This mode of attachment may certainly also be concluded from Renault's last excellent communication ("Nouvelles Recherches sur la Structure des Sphenophyllum," *Ann. d. Sc. Nat. Bot.*, 1877). My own observations on a beautiful spike from Wettin, give the same result.

But it must also be borne in mind that those spikes to which I have thought right to restrict the name Volkmannia, which in all probability belong to twigs with the foliage of Asterophyllites, have the same sessile, axillary sporangia, so far as can be determined. If this be correct, however, there can be no difficulty from this point of view in uniting these Volkmanniæ (not Sturs, which belong to Palæostachya) with the spikes of Sphenophyllum into a single group. This is a further corroboration of my formerly expressed conclusion, that the two form a group which must be removed from the Calamariæ.

On summing up the results of these critical comparisons, we find (what has not yet been thoroughly contradicted) that Sphenophyllum may be grouped under Lycopodiaceæ, anatomical structure and fructification alike removing it from Calamariæ. Only it becomes more and more impossible to dispute that the convenient generic names Calamites, Asterophyllites, &c., are purely provisional—unfitted, it is true, to show the real relations of the plants that bear them, but indispensable, in the great majority of cases, where the material is insufficient for complete investigation, important though it be. Plants with stems and leaves of undistinguishable appearance, especially in the ordinary state of preservation, but with such different fructifications as Calamostachys and Palæostachya, for instance, must retain their autonomy, and Sphenophyllum still more so. It is not every arborescent Calamarioid stem, not every so-called Calamites that belongs to this botanical genus. It has now become very evident that what has been hitherto termed Asterophyllites, comprises plants of several groups; yet Cingularia and Bowmannites had already been distinguished, though they both possessed the stem of Asterophyllites, as regards external structure and foliation. We see that the practical difficulties in the distinction and nomenclature of fossils are augmented; but this lies in the very nature of the case. It is thus unnecessary to doubt the co-existence of Asterophyllites and Sphenophyllum twigs on one plant, as Stur has observed, without going on to admit his conclusions that Asterophyllites, as a whole, is identical with Sphenophyllum, and that both are Calamites. If the spikes cited are really Calamostachys (Bruckmannia, Stur) and Palæostachya (Volkmannia, Stur), this would show the distinctness of the fossils regarded by him as identical. Renault has found both macrosporangia and microsporangia on the same spike of Sphenophyllum; this tells against the view that Volkmannia, Stur (that is, in this case, the Sphenophyllum spike) is the female, and Bruckmannia, Stur, the male fruiting spike of one and the same plant. It will be seen how desirable it is to have further cautious investigation and careful publication upon the interesting find on which we are to base such far-reaching conclusions as those which Stur has lately drawn.

[1] On this point M. Renault is mistaken; they differ in the chief features which distinguish Sphenophyllum from Asterophyllites, viz., in the number and shape of the leaves and in the number of the separate vascular bundles given off to these leaves.—W. C. W.

ANTHROPOLOGICAL INQUIRY IN FRANCE

THE published reports of the proceedings of the Société d'Anthropologie of Paris, for the year ending in the autumn of 1878, testify as usual to the diligence and zeal of a large number of its members. Limiting ourselves to the notice of papers which deal with questions of French local palæontology and sociology, we will begin our *résumé* by drawing attention to the interesting labours of M. Prunières, who has laid before the Society the result of several years' exploration of the Beaumes-Chaudes caverns in Lozère, the largest prehistoric ossuary yet brought to light. Here he recovered the remains of

300 individuals, besides a mass of more than 200,000 fragmentary pieces. These human bones were white, showing no trace of the action of fire, although charred animal bones and broken pottery were found near them, the whole being embedded in stalagmite and stalactite as hard as marble. The dolichocephalic crania, protruding jaws, and flat tibiæ, showed a close affinity to the Cro-Magnon and l'Homme-mort remains; and M. Prunières is of opinion, that at Beaumes-Chaudes we have evidence of the existence of a race differing essentially from those which have occupied France in modern times, and even from the pre-historic men of the neighbouring dolmens of Lozère. In the latter, and in the dolmen founders of western France generally, he recognises the more civilised agricultural race which waged war against the ruder cave-men, and finally exterminated them. And he believes we have indisputable evidence of this conflict of races in the fact, that while several of the Beaumes-Chaudes bones were found to have slender flints impacted in them of the kind discovered in the dolmens, and differing wholly from the flint arrow heads characteristic of the cave-men, only a few of the same form of silex were found lying loose in the *débris*, and these he thinks we may fairly assume to have become detached in the process of decomposition from the softer tissues of the body, in which they had been arrested. Some of the crania exhibited a hitherto unnoticed form of double-trepanning of the right and left parietals, whose different cicatrices appeared to show that a considerable interval had elapsed between the first and second operation, which probably was the pre-historic surgical remedy for convulsions, and all affections included in later ages under the term "possession."

At Cravanche, near Belfort, a somewhat similar mortuary cavern has been examined by M. Bernard. Here the seven nearly perfect crania, extricated from an enormous mass of human bones, were all remarkable for their large cubic capacity (1680 centims.), the vertical index being 70, and the cephalic index 72. No iron or bronze implements were found, but numerous flints and serpentine rings were obtained. M. Leguay has done much to settle the question of the implements with which pre-historic men cut and carved schist and bone objects, by his successful imitation of a schist amulet, found by M. Rivière 24 feet below the floor of the Mentone caverns. In the fabrication of this spurious antique, M. Leguay used some of the flint knives so common in pre-historic caverns, which are blunt at the extremity, and curved towards the middle; with these he was able after a little practice to effect all the graving and cutting required to produce exact facsimiles of the pre-historic originals, and he believes, that wherever we find an excessive accumulation of flint-splints and fragments we have evidence of being on the site of a work-place or factory, rather than that of an ordinary primæval dwelling. It should be observed that M. Broca has used a cave-silex in trepanning a dog, which recovered with less than ordinary inconvenience from the operation. The neighbourhood of Luchon in the French Pyrenees has long been recognised by geologists as an admirable locality for the study of glacial action, evidences of which abound in the moraines and huge erratic boulders which cover the southern flank of Mont Espiaup, and block up the valley of the Oô; but it is only within the last few years that French archæologists have directed their attention to the innumerable megalithic remains which occur in the district, and which, as in other parts of the Pyrenean range, still maintain some of their ancient sanctity in the eyes of the peasantry. These remains have now been carefully studied by MM. Piette and Sacaze, the results of whose most important investigations were given in detail in a paper printed in *Bulletin d'Anthropologie*, tome 12, série 2, 1877. From these and subsequent researches, it would appear that the megalithic circles and rows have generally been made to follow the direction of the granite boulders, smaller stones having been used to complete the desired outlines. Under the cromlechs and within the stone circles numerous urns were found, containing for the most part only ashes; but in one instance, two bronze armlets, nearly identical with those of the Swiss lake dwellings, were discovered. Local tradition and still existing practices warrant the assumption that the so-called fire-stones—menhirs—were long associated with fire-worship; while the form of certain stones, which in defiance of the clergy continue to be made the centres of various local games and dances, together with the character of the mysterious and hidden ceremonials which are practised in relation to them, as clearly point to a not wholly eradicated observance of phallic rites. Near Maintenon, M. Lamy has succeeded in proving the existence of menhirs and dolmens, and has opened a burial chamber in which, besides two adults, he found a child's skeleton standing upright in the grave.

The attention of several members of the Society has been directed to the improvement of instruments for the attainment of reliable craniometrical determinations; and among these the double graduated square, invented and used by Dr. Harmand during his extensive travels in India and China, and the portable cephalometer, specially designed by Dr. Le Bon for the correct measurement of the vertical height of the head, appear to have met with the greatest approval. The former is described at length in the tome 12, sér. 2 (1877), and the latter in tome 1, sér. 3 (1878) of the *Bulletin d'Anthropologie*. M. Broca has drawn attention to the injurious action of alcohol on the preservation of crania, and recommends the use of nitric acid, followed by immersion in glycerine before the varnish is applied. M. Personne on the other hand prefers the use of chloral, under the action of which he has found that the cranial bones contract, and become as hard as wood. Much interest has been excited in the Society by the report of M. Thulié, on the appearance of the brain of M. Asseline, one of its members who had belonged, like many of his anthropological confrères, to the Société d'Autopsie mutuelle. M. Asseline died in 1878, at the age of 49. He was a republican and a materialist; was possessed of enormous capacity for work, great faculty of mental assimilation, and an extraordinarily retentive memory; and had a gentle benevolent disposition, keen susceptibilities, refined taste and subtle wit. As a writer he had always displayed great learning, unusual force of style and elegance of diction, and in his intercourse with others he had been unassuming, sensitive, and even timid. Yet the autopsy showed such coarseness and thickness of the convolutions that M. Broca pronounced them to be characteristic of an inferior brain. The fossa or depressions, regarded by Gratiolet as a simian character, and as a sign of cerebral inferiority, which are often found in women, and in some men of undoubted intellectual inferiority, were very much marked, especially on the left parieto-occipital. But the cranial bones were at some points so thin as to be translucent; the cerebral depressions were deeply marked, the frontal suture was not wholly ossified, a decided degree of asymetry was manifested in the greater prominence of the right frontal, while, moreover, the brain weighed 1,468 grammes, *i.e.* about 60 grains above the average given by M. Broca for M. Asseline's age. The apparent contradictions between the weight of the brain and the great development of the anterior parts on the one hand, and the marked character of the parieto-occipital depressions on the other, attracted much attention, and the members of the Société d'Anthropologie have been earnestly invited by M. Hovelacque, in furtherance of science, to join the Société d'Autopsie, to which anthropology is already indebted for many highly important observations. This Society is forming a collection of photographs of its members which are taken in accordance with certain fixed rules.

M. Chervin has drawn attention to the frequency of stammering in the south of France, where from 12 to 13 cases are noted for every 1,000, while in the eastern departments the proportion is only 1 for every 1,000. It has been assumed that the defect was in many cases simulated to avoid the conscription; but according to the Abbé Petitot, there are two districts in the Bouches-du-Rhone, where all the inhabitants (15,000), stammer. This he ascribes to long continued inter-marriages among the communities, and to a consequent degeneracy of the race; and M. Chervin is of opinion that meningitis, induced by the great solar heat, which occasions so high an infantile mortality in this region, may possibly, when not fatal, leave an exceptionally great tendency to stammering.

M. Broca, with his usual diligence, has continued to work out his system of *cerebral topography* in man and in the lower animals; and he has lately presented the society with a large number of cranial moulds, on which every convolution, lobe, or other part, is distinctly marked by different colours, in accordance with sex, age, and race. M. Broca has also made the difference of position of the occipital foramen in man and animals the subject of two interesting papers, the former of which was laid before the society in May, 1877. Following up the investigations of Daubenton, who, as early as 1764 made this a subject of inquiry, M. Broca, after a long course of determinations which he gives in detail, has summed up the results of his labours in the proposition that while in all animals but man the orbito-occipital angle is *constantly positive*, in man it is almost always

negative. It is invariably so in European races, where the differences oscillate between -5° and -39°. In the inferior races it may amount to $+5^\circ$; in adult anthropoids on the other hand, the minimum is found as high as $+32$, while in some gorillas it amounted to $+45$. In women the orbito-basilar angle is habitually from 2 to 3 degrees less than in men.

The decrease in the population of France still continues to excite much speculation. In tome 12, sér. 2, of the *Bulletins* will be found a suggestive paper by M. Després, on the relation between the birth-rate of a country and its enforcement of restrictive enactments intended to diminish the result of public immorality. In comparing Belgium with France a difficult question suggests itself in the fact, that while both countries are under sanitary official supervision, and Belgium next to France has the lowest birth-rate, it has 279 legitimate births against every thousand married women between the ages of 15 and 50, although France has only 174 in the 1,000. The latter has, however, the large number of 140 married women of those ages in every 1,000, while the former has only 105 in the 1,000. In England, on the other hand, before the enactment of any sanitary restrictions, 248 legitimate births were registered for every 1,000 married women of the given ages, (the proportion of married women from 15 to 50 being 133 in the 1,000). But while in this country 120 for every 1,000 men marry between the age of 20 and 25, in Belgium only 33, and in France not quite that number, out of every 1,000 men marry at the same age. This later marriage of the men M. Després regards as an important factor in the lowness of the French birth-rate.

VOLCANIC PHENOMENA AND EARTHQUAKES DURING 1878

THE statistical review of volcanic phenomena during 1878, which Prof. Fuchs has recently published, and which forms the continuation of many previous statistical accounts of the same nature (see NATURE, vol. xv. p. 557, and vol. xviii. p. 241) shows the unusually large number of *twelve* eruptions in the course of the year. Most of them occurred in remote localities and gave evidence of the activity of volcanoes which were generally but little known, and which are all difficult of access. It is true, however, that Mount Vesuvius also, the last eruption of which had taken place in 1872, but which already during 1877 had shown symptoms of the re-awakening of the volcanic process, again entered into a period of activity on April 20, 1878. The mountain ejected ashes, frequent slight shocks occurred, a thick column of smoke ascended, and at the end of September a scanty flow of lava took place. This increased during the night of September 22-23 and the lava descended as far as the Atrio del Cavallo; but afterwards the volcanic activity sank down into the ordinary solfatara-state, which was only interrupted by little periodical explosions on October 11, and by the flow of little streams of lava from November 1 to November 9.

At the southern point of South America active and hitherto unknown volcanoes were repeatedly seen by passing ships, viz. on January 10 and 18; one of them is situated upon the middle island in the English Narrows, the other on the South American continent in about 48° 56′ lat. S.; this one was conspicuous by a majestic column of smoke, ejected from a high snow-clad mountain, and rising to a height of some 300 metres.

At the same time a great eruption occurred in the island of Tanna, the well-known and very active volcanic island in the archipelago of the New Hebrides. On January 10, at 10 a.m., between the so-called Sulphur Bay and the old crater, a new eruption cone formed; the outbreak was accompanied by a mighty tidal wave which inundated a great part of the island. In spite of its violence the eruption lasted only a short time, but on February 4, a second outbreak followed which also did great damage.

Simultaneously yet another eruption happened. Its seat was the large island of Birara, in the group of New Britain. The northern part of the island was completely devastated, and its coasts rendered inaccessible through enormous masses of pumice stone, which covered the sea for many miles. Formerly, no volcano had been known there. We have repeatedly referred to the masses of floating pumice stone in the vicinity of the Solomon Islands, through which, as Captain Harrington reported, ships had to force their way for two or three days. It is very probable that this pumice stone originated from the eruption on Birara, and not from some submarine eruption, as was generally supposed at the time of the occurrence. It is true that there are two volcanoes in the Solomon Islands, the Semoya and the Lammat upon the island of Guadalcanar, but from neither were any eruptions reported during 1878.

The third eruption of February, took place from the volcano Isluga in South America (lat. 19° 10′, S), which mountain had been inactive since 1869. The outbreak was accompanied by a fearful earthquake, and so great were the masses of lava ejected that the villages of Cariquima, Carima, Sotoca, and Chiapa, all situated at more than five leagues' distance from the volcano, were completely destroyed by the incandescent streams.

Smaller volcanic eruptions occurred from Mount Hecla (from February 27, to the end of March), from the Asamayama in Japan, from the Cotopaxi near Quito (in October), from the Tepaco, the Sitna, and the Isalco in San Salvador. The eruptions in the Aleutian and Society Islands were of greater importance. In the volcanic series of the Aleutian islands, the volcanoes on Amukta, Tscheguluk, and the Vsevidok volcano (almost 2,800 metres high) on Umnak were in eruption. In the Society Islands, according to the report of Captain Evers, the islands of Raiatea, and Borabora were completely devastated by the action of volcanoes.

At the end of the list of lava-eruptions Dr. Fuchs records the great mud-eruption of one of the well-known mud-volcanoes near Paternò in Sicily. After repeated shocks of earthquake in the province of Catania spreading over two months, this eruption began on December 10, numerous craters ejecting streams of mud with great noise. Several of these craters were continuously active, as the mud was of little consistency, and freely permitted the ascending gases to escape. The others had explosions from time to time, as the crater basin was filled with much thicker mud, which prevented the gases from passing upwards until their tension was sufficiently high, and they ejected the mud in high rays. At the end of the year this mud-eruption was still progressing with unabated force.

The number of earthquakes reported during 1878 amounts to 103. But amongst these there are many complete earthquake-periods during which shocks and oscillations lasted with short intervals for hours, days, and even for several weeks in the same locality. If we would or could count all the separate shocks which occurred, a very high total would be reached. Thus in the comparatively unimportant earthquake of Zengg twenty shocks were counted, and in the great earthquake of Terapaca in the night of January 23 no less than forty shocks, while the oscillations lasted here almost without interruption until April 12. An earthquake on the island of Tanna (New Hebrides) lasted for four weeks, and in the province of Catania the oscillations succeeded each other almost without interruption from October 4 to November 19.

The earthquakes were most frequent in winter and autumn, thirty-nine occurring in winter, twenty-six in autumn, and nineteen each in summer and spring.

The most violent and most destructive of all these phenomena happened on January 23 in that district of Peru and Bolivia in which the terrible earthquake of 1868 took place. The province of Terapaca suffered more than any other. Here, with the earthquake of May 9, 1877, which in violence was hardly surpassed by that of 1868, a great and considerably extended period of frequently-recurring oscillations had begun, amongst which the earthquake of January 23, 1878, was prominent by its particular force. At Iquique it began at 7.55 P.M., and the shocks continued during the whole night. As usual, the subsequent tidal-wave did still greater damage than the earthquake itself, and this was particularly the case at Arequipa, Pica, Mantilla, Pisaqua, Arica, and Terapaca.

The earthquake on October 2, in the southern part of the republic of San Salvador, was also very violent. In the town of Incuapa almost all the houses were destroyed, and many of the inhabitants perished. In the vicinity a number of villages disappeared entirely. The motion of the soil was first undulatory and ended with a terrible shock.

Of European earthquakes the following must be mentioned specially:—

On January 28, about noon, an earthquake shook the north-western part of France and the south of England. It was particularly distinct in Normandy, at Rouen, Havre, and Dieppe. Even in Paris the shock was so considerable that several houses were endangered. In England it occurred between 11.45 and 11.50 A.M., and was observed at Greenwich, London, Brighton, Southampton, Cowes, and several other places.

Repeatedly shocks were felt in north-western Switzerland and at the south-west corner of the Black Forest. The first and more marked phenomenon happened on January 16, and con-

sisted of several shocks separated by short intervals. These shocks were noticed at Basel, Brugg, Solothurn, on the Swiss side of the Rhine, and at Lörrach, Schopfheim, Waldshut, &c., on the Badish bank. They recurred at Basel on January 17, and on March 29 they were again felt in the whole area described, and then even at Freiburg and Strasburg.

Other instances of repeated earthquakes are :—

Innsbruck (January 3, 10, 11, February 2, August 9).

Gross Gerau (January 2, March 25).

Lisbon (January 26, 27, June 8).

Piemont (repeated shocks on November 25).

Constantinople, Ismid, and Brussa (continual shocks from 19 to end of May).

The damage done by the last-mentioned phenomenon at Ismid and Brussa on April 19 was very considerable; the little town of Esmé was quite destroyed, and many inhabitants lost their lives. The English fleet, which happened to be anchored in the Bosphorus at the time, noticed the oscillations, and on board of one of the ships it was believed that the others were making torpedo experiments, and consequently looked out for shelter.

Less remarkable by its violence than by its enormous extent considering its intensity, was the Low-Rhenish earthquake of August 26. The observations in this case were unusually exact and numerous, which gives additional interest to the occurrence. It began about 9 A.M., and was best observed in the city of Cologne. Here it consisted of an undulatory rising and sinking of the ground, which increased in intensity to such an extent that some buildings began to oscillate ominously. On the cathedral tower the smaller bell struck several times and the wavering pillars in St. Gereon's Church caused such a panic among the congregation, that all rushed out. In many parts of the city the walls of houses showed cracks. At the end of the oscillations a dull subterranean noise was heard and a second shock was observed by many persons. In almost all localities in the Rhenish Province, from Cleve and Emmerich to Kyllburg, Ottweiler, and Montjoie the observations of the phenomenon were similar to those made at Cologne; the same was the case on the opposite bank of the Rhine, at Düsseldorf, Wiesbaden, Münster, and other places. At Aachen (Aix-la-Chapelle) five distinct shocks were noticed; at Elsdorf (on the Neuss-Düren Railway) no less than eighteen until the morning of August 27; and at Düren and Buir their number was but little below this figure.

The area struck by the first shock, on August 26 at 9 A.M., may have measured over 2,000 geographical square miles, as its outlines may be indicated as follows:—Arnsberg and Hanover in the north, Offenbach on the Main and Michelstadt in the Odenwald in the south-east, Strasburg, Paris, and Charelville in the south, Liége and Brussels in the west, and Utrecht in the north-west.

Prof. Klinkerfues has collected the most reliable observations of time and reduced them to the meridian of Paris. According to these calculations the earthquake happened at Cologne at 8h. 38·7m., at Strasburg at 8h. 39·9m., at Göttingen at 8h. 40·9m., at Hanover at 8h. 42·4m., and at Paris at 8h. 45·0m. If the starting point of the oscillations according to number and intensity of the shocks be supposed to have been situated about 2·5 geographical miles to the west of Cologne, the above indications of time give a velocity of the earthquake in the ground of 6·78 geographical miles, with a probable error of $\pm$ 0·48 miles. The depth of the original starting-point is unknown. Prof. Klinkerfues is of opinion that it laid between 6·3 and 8·7 geographical miles from the surface. It is remarkable that the phenomenon was only noticed at the surface, and was all the more intense the higher the observer was above the ground. Many observations were made both at Cologne and at Hanover, which show that the oscillations were far more considerable in the upper storeys of houses than in the lower ones. At Remagen the shock was so great on the upper floor of the school-building that teachers and school-children rushed terrified into the street, while on the ground floor the phenomenon was hardly noticed; the workmen on the towers of Cologne Cathedral saw the scaffolding oscillate to such an extent that they feared for their lives, and a water-tank on the vault of the choir was almost entirely emptied. Yet not one of 1,100 miners working at a depth of 300 metres at Altessen noticed the least shock.

For a long time afterwards shocks occurred at Elsdorf and Buir. At the latter place they were observed on August 26, 27, 28, 29, September 2, October 24, December 3 and 10. Also in other places of the same area the shocks were repeated, so at Remagen (September 3), Wiesbaden (September 14), Osterrath and Crefeld (September 18), Cologne (December 10), Luxemburg and Namur (December 15).

With almost all earthquakes of slight intensity it is very difficult to determine to what class of earthquakes they belong. Thus in the Low-Rhenish earthquake no symptom points to any particular cause. We may surmise volcanic influence, because the most intense and most numerous shocks occurred near the north-western slope of the Eifel-plateau; but with perhaps greater reason we may look for the cause of the phenomenon in the Rheno-Belgian coal district. Altogether the earthquake of August 26 seems to be but a link in a great earthquake-period, which for some years past has been causing lasting changes in the coal-deposits of that neighbourhood. The names of Herzogenrath, Kohlscheid, Eschweiler, &c., recur in every one of Dr. Fuchs's yearly accounts, and apart from numerous weaker oscillations of small extent, considerable earthquakes occurred in this district from September 28 to November 12, 1873, and on June 24, 1877.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

It is stated that the draft charter of the proposed Victoria University has, in accordance with the request of the Lords of the Privy Council, been submitted to that body. According to this draft, the University would have the power of conferring upon all persons, whether male or female, who have pursued a regular course of study in any of its colleges and passed its examinations, all degrees which can be conferred by any other University of the kingdom, with the exception of medical degrees, the Privy Council having declined to confer power as to these at a time when legislation on the whole subject of medical degrees and the licensing power for the practice of medicine has been proposed to Parliament and still remains unsettled. The charter, it is stated, contains provisions for establishing a convocation of graduates of the University, with appropriate rights and functions.

In the late Higher Local Examinations of Cambridge University, Physiology and Experimental Physics were introduced as separate subjects in Group E for the first time. One student, Miss A. Johnson, of Cambridge, passed in Physics, and out of sixteen who entered their names in Physiology, in which subject Mr. J. N. Langley, Fellow of Trinity College, was examiner, eleven passed, but no candidate obtained the mark of distinction. Only three passed in Zoology out of eighteen candidates; but two were distinguished; the failures were about three-fifths of the thirty-four candidates in Botany, and three obtained distinction. Twenty-two passed in Geology and Physical Geography, five obtaining the mark of distinction. In the first class of Group E four students are placed: Miss C. E. Cross, educated at 56, Regent Street, Cambridge, is distinguished in Botany and Geology, and passes in Chemistry; Miss L. M. Passavant, of De la Haye House, Leeds, is distinguished in Botany and Zoology; the candidate numbered 294, Leeds, name not published, is distinguished in Geology and Zoology, and has passed in Physiology; Miss M. A. Broadhurst, Liverpool College for Girls, is distinguished in Geology and Chemistry. Six passed Second Class in Group E, and twenty-eight were placed in the Third Class, to attain which passing in one subject is required, no more than three to be taken in any one year; others may be taken in subsequent years. In Group C (Mathematics) only two obtained distinction, namely, A. G. Lee, Dedham, Essex, and C. E. Oldaker, Chesterton Road, Cambridge, and eight obtained a First Class. The award of Scholarships dependent on the results of this examination has not yet been known.

About three years ago publicity was given to a proposal by Mr. Holloway, of Oxford Street, to expend a considerable amount of money in the erection of a college for the higher education of women. Since that time Mr. Holloway has purchased about ninety-five acres of land at Egham, near Virginia Water, known as the Mount Lee Estate, and has vested the same in trustees. Before deciding upon the form of the building, Mr. Holloway and his architect, Mr. W. H. Crossland, visited the principal collegiate institutions in Europe, and during the past year the plans and specifications have been completed. We now learn that a contract has been actually signed by Mr. Holloway for the building of the college within four years, the contract price being upwards of 250,000*l*., exclusive of fittings

and furniture. The building will be in the form of a double quadrangle, 510 feet from east to west, and 350 feet from north to south. The main buildings will be five storeys in height, and there will be cloisters 10 feet in width on two sides of each quadrangle. The style is to be that known as French Renaissance, and will be carried out in Portland stone and red brick. The object and scope of the college have been the subject of great consideration, and Mr. Holloway has had the advice and assistance of a large number of persons interested in the education of women. The proposed constitution of the college, to be embodied in a trust-deed, will, among other things, set forth that its object is to afford the best education suitable for women of the middle and upper middle classes, and it is intended to be mainly self-supporting. The trustees are to be a corporate body with perpetual succession, and to have all the usual powers and privileges. The governing body will consist of twenty-one persons, to be appointed partly by the University of London and partly by the Corporation of London, and it is stipulated that a certain portion shall always be women. Religious opinions are not in any way to affect the qualification for a governor. It is the founder's desire that power by Act of Parliament, Royal Charter, or otherwise, should be eventually sought to enable the college to confer degrees, after due examination, and that until such power is obtained the students shall qualify themselves to pass the women's examination of the London University, or any examination of a similar or higher character which may be open to women at any of the existing universities of the United Kingdom. The curriculum shall not be restricted to subjects enjoined by any existing university. Instead of being regulated by the traditions and methods of former ages, the system of education should be mainly founded on studies and sciences which the experience of modern times has shown to be most valuable and as best adapted for the intellectual and social requirements of students. The governors will, therefore, be empowered to provide instruction in any subject or branch of knowledge which shall appear to them from time to time most suitable for the education of women; and the curriculum of the college will not discourage students who may desire a liberal education apart from the Latin and Greek languages. Proficiency in classics is not to entitle students to rewards of merit over others equally proficient in other branches of knowledge. It is intended to provide twenty founder's scholarships of the value of 40*l*. each, tenable for not more than two years in the college. No professor will be required to submit to any test concerning his or her religious opinion, and denominational theology is not to be taught. The principal of the college must be a lady, and duly qualified lady physicians and surgeons are to be resident in the college. Mr. Holloway has determined to personally superintend the erection of the building, and has agreed to provide an endowment fund of 100,000*l*., in addition to any fund that may be derived from the sale of such portion of the Mount Lee estate as may not be required for the purposes of the college.

THE following is the list of candidates successful in the competition for the Whitworth Scholarships, 1879, in connection with the Science and Art Department:—John Hardisty, engineer; George Harrison, millwright; Edward Shaw, engineer apprentice; John A. Simpson, engineer; John W. Geddes, mechanic; Sydney J. Harris, engine fitter; Thomas E. Sackfield, mechanic; John A. Brodie, engineer apprentice. As the result of the final competition of scholars appointed in 1876, Mr. Henry S. H. Shaw has received the first prize of 200*l*., and Mr. Jerdan Nichols the second of 100*l*.

THE first Siberian university at Tomsk will be definitely opened for the term of 1879-80. The Czarewitch has signified his intention of being present at the inauguration.

FROM a report which has been sent us of the awards made at the conclusion of the session of the Johns Hopkins University, we notice that out of twenty Fellows appointed for 1879-80, twelve were in physical and biological science, all of them from other colleges than the Johns Hopkins, one of them being from the University of Tokio, Japan. The public spirit of the president and professors is shown in the fact that they have subscribed 500 dollars to be divided as scholarships to two meritorious students next year. In consideration of marked ability in the study of mathematics exemplified during a year's residence in Baltimore and previously, the trustees have invited Miss Christine Ladd to continue her mathematical studies in this university, and have voted that she may receive an honorary stipend, equal to that bestowed upon those who are appointed to fellowships. The trustees promised their aid to a specified amount for the encouragement of a journal of philology, to be published under the editorial control of Prof. Gildersleeve. This will be the fourth serial encouraged by the trustees—the others being the *Journal of Mathematics*, under Prof. Sylvester; the *Journal of Chemistry*, under Prof. Remsen; the *Biological Papers*, under Prof. Martin. The *Chesapeake Zoological Papers*, edited by Dr. Brooks, were published at the cost of a few liberal citizens of Baltimore. Arrangements have been matured for the continuance of the Chesapeake Zoological Laboratory during the ensuing year. The United States Fish Commission, under Prof. S. F. Baird, and the Maryland Fish Commission, under Major T. B. Ferguson, co-operate in this laboratory with the Johns Hopkins University.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, August 4.—M. Daubrée in the chair.—**The following papers were read**:—On the recent tornado in the United States, and on records of Buffon's and Spallanzani's observations of whirlwinds, by M. Faye.—Remarks by M. Berthelot on M. Wurtz's paper on hydrate of chloral.—Secreting and circulating effects produced by the faradisation of the nerves which traverse the tympanum, by M. A. Vulpian.—Supplementary note on the theory of the pulsations of the heart and arteries and their registration, by M. Bouillaud.—On the origin of hail, and on some whirlwinds in which the air was drawn upwards, by M. Colladon.—On the theory of fertilisation, by M. Dechant.—Note on the rotation theory of heavenly bodies, by M. Mougeolle.—A number of communications relating to *Phylloxera vastatrix*, by MM. Gayon and Millardet, G. Foex, A. Quercy, Borel, and H. Barthélemy, were read.—Observations of the occultation of Antares on July 28 last, by C. Flammarion.—On the normal calorific spectrum of the sun, and of the incandescent platinum lamp (Bourbouze), by M. Mouton.—Some observations on M. Mouton's paper, by M. P. THURSDAY, AUGUST 21, 1879

WEATHER CHARTS FOR THE NORTHERN HEMISPHERE

WE present to our readers with this number a copy of the latest work of the United States Signal Office—the Monthly International Weather Chart of the Northern Hemisphere based on simultaneous observations. The copies are the first published for distribution in Europe, and are at our request furnished from Washington. The work marks an important step in meteorological progress. The origin and purposes of the chart and its connection with others are sufficiently set forth in the following extracts from the Annual Report of the Chief Signal Officer to the Hon. Secretary of War of the United States:—

"The proposition adopted at the congress of persons charged with meteorological duties, assembled at Vienna in 1873, and to the affect that it is desirable, with a view to their exchange, that at least one uniform observation, of such character as to be suited for the preparation of synoptic charts, be taken and recorded daily and simultaneously at as many stations as practicable throughout the world, has continued to have practical effect.

"By authority of the War Department, and with the courteous co-operation of scientific men and chiefs of meteorological services representing the different countries, a record of observations taken daily, simultaneously with the observations taken throughout the United States and the adjacent islands, is exchanged semi-monthly. These reports are to cover the territorial extent of Algiers, Austria, Australasia, Belgium, Great Britain, China, Central America, Denmark, France, Germany, Greece, Greenland, India, Italy, Iceland, Japan, Mexico, Morocco, the Netherlands, Norway, Portugal, Russia, Spain, Sweden, Switzerland, Turkey, Tunis, British North America, the United States, the Azores, Sandwich Islands, Malta, Mauritius, West Indies, South Africa, and South America.

"On July 1, 1875, the daily issue of a printed bulletin, exhibiting these international simultaneous reports, was commenced at this office, and has been since maintained. A copy of this bulletin is furnished each co-operating observer. The results to be had from the reports thus collated are considered as to be of especial importance. The bulletin combines, for the first time of which there is record, the labours of the nations in a work of this kind for their mutual benefit. There is needed only the assistance to be had from the naval forces of the different powers (that of the navies of the United States and of Portugal being as heretofore related already given to extend the plan of report upon the seas) to bring more fully within the scope of study observations practically extending around the northern hemisphere. This end is to a great extent already attained.

"In this connection the office has to acknowledge the cordial and valuable co-operation of the meteorological services of the different countries, represented as follows:—

"Algiers, by General Teissier, Commandant Supérieur du Génie; Austria, by Prof. Dr. Julius Hann, Director of the Imperial and Royal Central Meteorological Institute at Vienna; Belgium, by J. C. Houzeau, Director of the Royal Observatory at Brussels; Great Britain, by Robert H. Scott, F.R.S., Secretary of the Meteorological Council, London; Alexander Buchan, M.A., F.R.S.E., Secretary of the Scottish Meteorological Society, Edinburgh, and the respective observers; Costa Rica, by Señor Federico Maison, Director of the Central Office of Statistics and Meteorology; Denmark, by Capt. N. Hoffmeyer, Director of the Royal Danish Meteorological Institute at Copenhagen; France, by U. J. Le Verrier, Director of the Paris Observatory, Prof. E. Mascart, Director of the Central Meteorological Bureau of France, and the respective observers; Germany, by Prof. Dr. Geo. Neumayer, Director of the German Naval Observatory, Hamburg; Greece, by Prof. Dr. J. F. Julius Schmidt, Director of the Royal Observatory at Athens; India, by H. F. Blanford, Meteorological Reporter to the Government of India; Italy, by the Minister of Agriculture, Industry, and Commerce, and the respective observers; Japan, by the Imperial Meteorological Observatory, and the Imperial University of Tokei, Japan; Mexico, by Señor Mariano Barcena, Director of the Central Meteorological Observatory in the City of Mexico, and the respective observers; Netherlands, by Prof. Buys Ballot, Director of the Royal Meteorological Institute of the Netherlands at Utrecht; Norway, by Prof. H. Mohn, Director of the Royal Norwegian Meteorological Institute at Christiania; Portugal, by J. C. de Brito Capello, Director of the Meteorological Observatory of the Infante Don Luiz, at Lisbon; Russia, by Prof. H. Wild, Director of the Imperial Central Physical Observatory of Russia, at St. Petersburg; Spain, by Antonio Aguilar, Director of the Royal Observatory at Madrid, and the respective observers; Sweden, by Prof. R. Rubenson, Director of the Royal Swedish Meteorological Institute at Stockholm, and of Dr. H. H. Hildebrandsson, Chief of the Meterological Division of the Upsala Observatory; Switzerland, by Prof. R. Wolf, Director of the Observatory at Zurich, and of Prof. E. Plantamour, Director of the Observatory at Geneva; Turkey, by A. Coumbary, Effendi, Director of the Central Observatory at Constantinople, and of Prof. C. V. A. van Dyck, Superintendent of the Lee Observatory at Beirut; Canada, by Prof. G. T. Kingston, Director of the Magnetic Observatory at Toronto, and Superintendent of the Meteorological Office of the Dominion of Canada, and the respective observers; United States Navy, by Navy Department, through Rear-Admiral Daniel Ammen, and Commodore W. D. Whiting, U.S.N., Chiefs of the Bureau of Navigation; and by individual observers at other points.

"The Office has to regret the death since the date of the last annual report of the following distinguished colabourers in the work:—Urbain Jean Joseph Le Verrier, Director of the Paris Observatory, Prof. Ernst Quetelet, Director of the Royal Observatory at Brussels, Prof. Edward Heis, of Münster, and Prof. Pietro Angelo Secchi, of Rome.

"A number of observations taken on vessels at sea to complement the synchronous reports of the service, and at the request of the department, have been received on the form provided for the purpose, paper 49. Their utility is evident in the study of storms approaching our coasts or which endanger vessels sailing from our ports.

"The co-operation of the navy of the United States in the taking of observations simultaneously with the system adopted at this office, wherever naval vessels of the United States may be, as assured by the general order of the Secretary of the Navy, dated December 25, 1876, has largely increased the data of this class. This co-operation has been skilfully rendered by the Navy Department and the United States Navy, through the Chief of the Bureau of Navigation.

"The people of the United States are thus the first nation whose army and navy co-operate, as all armies and navies should, under official orders, in the taking of simultaneous observations wherever the forces may be.

"In view of the existence of the system of simultaneous reports to be made at sea by the vessels of the naval and commercial marines of the United States and other nations, and to provide for its extension, carefully tested

barometers of the best make have, since the date of the last annual report, been prepared and located, as standards, at the ports of New York and San Francisco.

"These barometers have been publicly located to afford means for comparison of the ships' barometers of the shipping of all nations. The instruments, while carefully guarded, are easily accessible. Public notice is given of the location, and a sergeant of the Signal Corps attends daily to give information and to take charge of any ship's barometer which may be brought for comparison (Paper 48).

"The standard barometer for the use of shipping in the Atlantic Ocean is located at the Maritime Exchange, in New York City; the standard barometer for the use of shipping in the Pacific Ocean is located at the Merchants' Exchange, in the city of San Francisco.

"The officers of the Signal Service at the different cities and ports of the United States and upon the sea-coast offer every facility and aid in their power to the vessels of any nation.

"With the plans for charting now adopted at this office, and with the reports now received here, it appears that the meteoric changes occurring over a great portion of the continents north of the equator can be charted with an accuracy sufficient to permit careful and valuable study. This charting to be of the best attainable value, must be supplemented from the records of observations had on the seas. A ship at sea becomes one of the best of stations for a simultaneous system. The value of the record is enhanced by the change of the ship's location occurring within each period of twenty-four hours. There is no sea-going vessel but which carries human life, and each ought to carry by compulsion, if need be, meteorological instruments. The smallest craft, in caring for its own safety, may use them enough to add to the value of the most extensive record. There is no nation without interest in the work proposed to be based upon exchanged simultaneous reports, and none has hitherto hesitated, when the subject has been properly presented, to aid in a duty which, so easily done as to require very little effort on the part of any one person, has for its object a good to mankind. The work cannot, from its nature, be for the selfish good of any section.

"A number of the great steamship companies, foreign and domestic, operating the principal commercial sea-routes, have promised and will give their powerful influence and aid.

"The office has the co-operation of the Pacific Mail Steamship Company, through its agents, Williams, Blanchard and Co.; the White Star Line, through its agents, Ismay, Imrie and Co., Liverpool, and R. J. Curtis, New York; the Occidental and Oriental Steamship Company, through its president, George H. Bradbury; the North German Lloyd, through its agents, A. Schumacher and Co.; the American Steamship Company, through its president, H. D. Welsh; the Red Star Line, through its president, James A. Wright, and the Allan Line, through its agents, A. Schumacher and Co.

"The United States bear, in the cases of all maritime observers co-operating in this system, all expenses for forms, postages, &c., when so desired, and not infrequently, and, when necessary, loan the required instruments.

"The number of observations made daily on separate vessels at sea is 100 (Paper 13).

"Research has already gone far enough to indicate the paths by which, if it cannot be directly predicted, it can at least be studied, to learn what sequences to follow conditions reported on or near the eastern coast of Asia, or on the Pacific, will be found on our own western coasts.

"Similar studies will have reference to our own southern and eastern coasts, and to the western coasts of the European continent. The time cannot be far distant when vessels leaving any Atlantic port may be informed whether any notable disturbance exists at sea and where it is likely to threaten the voyage.

"The establishment of permanent ocean stations in lines traversing the oceans over or near the telegraphic cables, and in telegraphic communication with either continent, is not considered impracticable, and has been referred to in a preceding report.

"There is reason to hope that a progress has been made which will eliminate from the study of practical international meteorology some of the difficulties hitherto encountered.

"There are grounds to hope also that the atmospheric conditions and changes of condition can be charted with sufficient accuracy over any extent of the earth's surface.

"If the hope has fruition, meteorological barriers will, as against study, practically cease to exist.

"A copy of the International Bulletin herewith (Paper 27) exhibits the character of the international reports, and that of the information had from each station. The chart accompanying this bulletin shows as nearly as practicable the location of the stations, and foreshadows the duties and reports had from them will make practicable. The number of stations reporting increases.

"While the stations are crowded in some localities, each is useful—each serving to check the work of the other, and each aiding to close the gaps the failure of other stations might sometimes cause. The work is not likely to be abandoned by those in the different countries who have taken part in establishing it, and who share its benefits. If it serve no other purpose than to maintain, as it does, the pleasant co-operation of those charged with the meteorological duties of the different countries, it would be of value. It is hoped that by systems of observations thus extensive, generalisations may be had to permit the announcement of meteoric changes for periods longer in advance than have been hitherto practicable.

"The average number of daily simultaneous observations now made in foreign countries is 293. The total number of *stations* on land and *on vessels at sea from which reports* are entered in the bulletin regularly is 557. The co-operation of the different nations secured by this plan of exchange, as above described, renders the additional cost to the United States of the grand system of reports it makes possible but little more than that of the cost of the preparation, paper, and binding of the International Bulletin and the accompanying charts, a cost which would have to be met in great part for the proper preservation of the records themselves even if the bulletins were not distributed.

"The Chief Signal Officer is gratified to announce in this report that the work of the collection of the reports of international simultaneous observations, carried on in foreign countries in co-operation with the United States, as well as within the territories of the United States and upon the seas thus above referred to, has in the year just passed so far progressed as to have attained one principal result for which it was set on foot. On July 1, 1878, it became possible for the first time in the history of this office to commence the issue, on that date, of a daily international weather map, charted daily and issued daily, each chart based upon the data appearing upon the International Bulletin of simultaneous reports of similar date. The charting extends around the world, and embraces for its area the whole northern hemisphere.

"The daily issue of a chart of this kind, thus daily issued for the first time by the United States, is without a precedent in history. It exhibits the co-operation, for for a single purpose, of the civilised powers of the world north of the equator.

"The studies such charts make possible, the improvement which will come as the work progresses and the area of the chart is better filled with reports of observations carefully elaborated, are fully appreciated by scien tific men. The questions as to the translations of storms

from continent to continent, and of the times and directions they may take in such movements; the movement of areas of high and of low barometer; the conditions of temperature, pressure, and wind-direction existing around the earth at a fixed instant of time, permitting thus the effects of day and night to be contrasted; the distribution and amount of rainfall, and other studies, many and valuable, only suggested by this enumeration, may be by such studies settled. It seems not impossible that in the future questions of climatology, and perhaps others bearing upon the prediction of weather changes far in advance of the time at which these changes may happen, or questions of the character of coming seasons even, may be answered by the researches these charts will make practicable.

"The very great aid and material furnished in this elaborated form gives to the search for generalisation, or for data in the support of theories, was referred to in the last annual report. In frequent cases little more than collation is necessary.

"As a means of better combining the work and the interests of the several nations; of certainly securing that co-operation at sea which will enable the lines of the charting to be drawn as fully and as well over oceans as over continents; and which will give the world ultimately a knowledge as practical of the movement of areas of disturbance in the midst of the seas as is now had of such movements on some continents, the undertaking is of much importance.

"It is an advantage of the charting draughted from simultaneous reports that studies by normals, not possible in any other way, can be made. The normal pressure, temperature, &c., arrived at from observations taken at any one place, at the same and a fixed instant of time every day, become established as to that place and time with accuracy. Many causes of error are eliminated.

"The intercomparison of these normals with the normals taken at other places simultaneously with the first and under the similar condition that the normals to be found for those places are to be from observations taken at those places at a fixed time and on every day, gives results reliable and different from those to be had by the use of normal readings arrived at in any other manner. Normals for the year, for the season, and for the month, may be determined by such procedure. The comparison of such normals will show in the case of abnormal changes in any district or section for any season whether and how they are compensated by compensating variations elsewhere. There are interesting studies as to what sequences there may be to follow such atmospheric variations occurring over any region or country—either in that region or country, or elsewhere—and how and where the compensating variations occur, and with what concomitants or sequences of meteoric changes.

"There is the hope to gain in this way or by studies such study will suggest information to affect the commercial and agricultural interests of the world.

"There is the further hope that as it is more fully realised by the different peoples, how close in the future the practice of such investigations draws, each member of the family of nations will find its own interests in labours of this description, and draw more closely the bonds and join with energy in a work which has so begun to connect them. The undertaking, world-wide in extent, is capable of rendering a world-wide benefit."

The chart before our readers bears information condensed from thirty—one for each day of the month—of the world weather charts above described, and exhibits one path of study to be pursued. It shows for one month the lines of mean pressure, mean temperature, and average wind direction on land and sea within the limits of civilisation on the Northern Hemisphere. The appearance of the map marks the commencement of the first actual and current study of the atmosphere of the whole Northern Hemisphere for practical use.

It will be noticed from the Report that the Chief Signal Officer, General Myer, while pressing forward month after month his plan, commenced on the American Continent nine years ago—in 1870—of mapping by weather charts and simultaneously the Northern Hemisphere, and fixing its success, reaches out a helping hand to every people. The Report asks all nations to stand side by side with the United States in carrying forward the work now marked out, and announces that so far as the United States is concerned the least of the co-operators shall receive the perfected work as fully as the greatest. Every separate observer or ship at sea co-operating in this work receives a copy of the chart he has helped to make. Aside from any national benefit the work is to benefit the human race.

THE BRITISH ASSOCIATION

THE Forty-ninth Annual Meeting of the British Association was opened yesterday at Sheffield, under the presidency of Prof. Allman, F.R.S. The new secretary, Mr. J. E. H. Gordon, has made several innovations in the conduct of the business of the Association, which, when fairly established, will no doubt be decided improvements.

At the end of last week all the arrangements for the meeting were in an unusually forward state. Circulars had been sent to every member of the Association, and all the more prominent members who had replied have been well provided for by private hospitality, unless they desired to be otherwise accommodated. It is expected that the meeting will in all respects be a very good one. At all events, no efforts have been spared by the town of Sheffield to make it so, and the local secretaries and other officers have been at their posts from soon after eight in the morning to late every evening. A handy Guide-Book to Sheffield and its neighbourhood has been compiled for the special use of those attending the meeting of the Association.

There will be an excellent display of all the more recent scientific inventions at the second *soirée* given by the Local Committee on Tuesday the 26th. Independently of the large number of excursions arranged for Saturday the 23rd, and Thursday the 28th, most of the leading manufactories will be opened to the members, or will be visited by parties invited for special days. The Firth College, the gift to the town of Mr. Mark Firth, will now be used for the first time, and will be found admirably adapted for the reception-room and offices. It is to be formally opened for educational purposes in October by Prince Leopold. At one time much anxiety was felt with reference to this building. The long and severe winter delayed operations so much, that but for subsequent great energy it could not have been finished for the meeting. For the last two weeks it has been used for the temporary offices of the Association, though the secretaries and others have been compelled to carry on their business along with all sorts of workmen. If, as originally fixed, the meeting had commenced on August 6, it would have been almost impossible to have used the college for the reception-room.

The Local Committee have had a good deal of trouble, we believe, in the matter of lodging accommodation; but this has happily been surmounted. The citizens of Sheffield have most liberally responded to the request for hospitality, and special arrangements have been made for the adequate refreshment of members who conscientiously attend to the thirsty and appetising work of the Sections; for it seems Sheffield is rather

scantily provided with hotels and restaurants. The list of excursions seems unusually large, there being twenty-four in all for Saturday the 23rd, and Thursday the 28th; all the arrangements for these bespeak the greatest thoughtfulness for the comfort of the members. On Friday evening, the 22nd, a twilight exhibition of Bessemer steel manufacture is to be shown to 100 members at the Phœnix Bessemer Works, Iccles, Rotherham, and on Wednesday next Nunnery and Aldwarke Collieries will be visited.

Ample entertainment has been arranged for in the way of banquets and *conversazioni*, and on Sunday the Archbishop of York and Canon Tristram are to preach in the Parish Church. Altogether the Sheffield meeting promises, if not to be unusually large, to be thoroughly satisfactory so far as local arrangements go.

Inaugural Address of Prof. G. J. Allman, M.D., LL.D., F.R.S.S.L. and E., M.R.I.A., Pres. L.S., President.

It is no easy thing to find material suited to an occasion like the present. For on the one hand there is risk that a presidential address may be too special for an audience necessarily large and general, while on the other hand it may treat too much of generalities to take hold of the sympathies and command the attention of the hearers.

It may be supposed that my subject should have been suggested by the great manufacturing industries of the town which has brought us together; but I felt convinced that a worker in only the biological sciences could not do justice to the workers in so very different a field.

I am not, therefore, going to discourse to you of any of those great industries which make civilised society what it is—of those practical applications of scientific truth which within the last half century have become developed with such marvellous rapidity, and which have already become interwoven with our everyday life, as the warp of the weaver is interwoven with the woof. Such subjects must be left to other occupiers of this chair, from whom they may receive that justice which I could not pretend to give them; and I believe I shall act most wisely by keeping to a field with which my own studies have been more directly connected.

I know that there are many here present from whom I have no right to expect that previous knowledge which would justify me in dispensing with such an amount of elementary treatment as can alone bring my subject intelligibly before them, and my fellow-members of the British Association who have the advantage of being no novices in that department of biology with which I propose to occupy you, will pardon me if I address myself mainly to those for whom the field of research on which we are about to enter has now been opened for the first time.

I have chosen, then, as the matter of my address to you to-night, a subject in whose study there has during the last few years prevailed an unwonted amount of activity, resulting in the discovery of many remarkable facts, and the justification of many significant generalisations. I propose, in short, to give you in as untechnical a form as possible some account of the most generalised expression of living matter, and of the results of the more recent researches into its nature and phenomena.

More than forty years have now passed away since the French naturalist, Dujardin, drew attention to the fact that the bodies of some of the lowest members of the animal kingdom consist of a structureless, semi-fluid, contractile substance, to which he gave the name of Sarcode. A similar substance occurring in the cells of plants was afterwards studied by Hugo von Mohl, and named by him Protoplasm. It remained for Max Schultze to demonstrate that the sarcode of animals and the protoplasm of plants were identical.

The conclusions of Max Schultze have been in all respects confirmed by subsequent research, and it has further been rendered certain that this same protoplasm lies at the base of all the phenomena of life, whether in the animal or the vegetable kingdom. Thus has arisen the most important and significant generalisation in the whole domain of biological science.

Within the last few years protoplasm has again been made a subject of special study; unexpected and often startling facts have been brought to light, and a voluminous literature has gathered round this new centre of research. I believe, therefore, that I cannot do better than call your attention to some of the more important results of these inquiries, and endeavour to give you some knowledge of the properties of protoplasm, and of the part it plays in the two great kingdoms of organic nature.

As has just been said, protoplasm lies at the base of every vital phenomenon. It is, as Huxley has well expressed it, "the physical basis of life." Wherever there is life, from its lowest to its highest manifestations, there is protoplasm; wherever there is protoplasm, there, too, is life. Thus, coextensive with the whole of organic nature—every vital act being referable to some mode or property of protoplasm—it becomes to the biologist what the ether is to the physicist; only that instead of being a hypothetical conception, accepted as a reality from its adequacy in the explanation of phenomena, it is a tangible and visible reality, which the chemist may analyse in his laboratory, the biologist scrutinise beneath his microscope and his dissecting needle.

The chemical composition of protoplasm is very complex, and has not been exactly determined. It may, however, be stated that protoplasm is essentially a combination of albuminoid bodies, and that its principal elements are, therefore, oxygen, carbon, hydrogen, and nitrogen. In its typical state it presents the condition of a semi-fluid substance—a tenacious, glairy liquid, with a consistence somewhat like that of the white of an unboiled egg.[1] While we watch it beneath the microscope movements are set up in it; waves traverse its surface, or it may be seen to flow away in streams, either broad and attaining but a slight distance from the main mass, or else stretching away far from their source, as narrow liquid threads, which may continue simple, or may divide into branches, each following its own independent course; or the streams may flow one into the other, as streamlets would flow into rivulets and rivulets into rivers, and this not only where gravity would carry them, but in a direction diametrically opposed to gravitation; now we see it spreading itself out on all sides into a thin liquid stratum, and again drawing itself together within the narrow limits which had at first confined it, and all this without any obvious impulse from without which would send the ripples over its surface or set the streams flowing from its margin. Though it is certain that all these phenomena are in response to some stimulus exerted on it by the outer world, they are such as we never meet with in a simply physical fluid—they are spontaneous movements resulting from its proper irritability, from its essential constitution as living matter.

Examine it closer, bring to bear on it the highest powers of your microscope—you will probably find disseminated through it countless multitudes of exceedingly minute granules; but you may also find it absolutely homogeneous, and, whether containing granules or not, it is certain that you will find nothing to which the term *organisation* can be applied. You have before you a glairy, tenacious fluid, which, if not absolutely homogeneous, is yet totally destitute of structure.

And yet no one who contemplates this spontaneously moving matter can deny that it is alive. Liquid as it is, it is a living liquid; organless and structureless as it is, it manifests the essential phenomena of life.

The picture which I have thus endeavoured to trace for you in a few leading outlines is that of protoplasm in its most generalised aspect. Such generalisations, however, are in themselves unable to satisfy the conditions demanded by an exact scientific inquiry, and I propose now, before passing to the further consideration of the place and purport of protoplasm in nature, to bring before you some definite examples of protoplasm, such as are actually met with in the organic world.

A quantity of a peculiar slimy matter was dredged in the North Atlantic by the naturalists of the exploring ship *Porcupine* from a depth of from 5,000 to 25,000 feet. It is described as exhibiting, when examined on the spot, spontaneous movements, and as being obviously endowed with life. Specimens of this, preserved in spirits, were examined by Prof. Huxley, and declared by him to consist of protoplasm, vast masses of which must thus in a living state extend over wide areas of sea bottom. To this wonderful slime Huxley gave the name of *Bathybius Haeckelii*.

Bathybius has since been subjected to an exhaustive examina-

[1] In speaking of protoplasm as a liquid, it must be borne in mind that this expression refers only to its physical consistence—a condition depending mainly on the amount of water with which it is combined, and subject to considerable variation, from the solid form in which we find it in the dormant embryo of seeds, to the thin watery state in which it occurs in the leaves of Valisneria. Its distinguishing properties are totally different from those of a purely physical liquid, and are subject to an entirely different set of laws.

tion by Prof. Haeckel, who believes that he is able to confirm in all points the conclusions of Huxley, and arrives at the conviction that the bottom of the open ocean, at depths below 5,000 feet, is covered with an enormous mass of living protoplasm, which lingers there in the simplest and most primitive condition, having as yet acquired no definite form. He suggests that it may have originated by spontaneous generation, but leaves this question for future investigations to decide.

The reality of Bathybius, however, has not been universally accepted. In the more recent investigations of the *Challenger* the explorers have failed in their attempts to bring further evidence of the existence of masses of amorphous protoplasm spreading over the bed of the ocean. They have met with no trace of Bathybius in any of the regions explored by them, and they believe that they are justified in the conclusion that the matter found in the dredgings of the *Porcupine* and preserved in spirits for further examination, was only an inorganic precipitate due to the action of the alcohol.

It is not easy to believe, however, that the very elaborate investigations of Huxley and Haeckel can be thus disposed of. These, moreover, have received strong confirmation from the still more recent observations of the Arctic voyager, Bessels, who was one of the explorers of the ill-fated *Polaris*, and who states that he dredged from the Greenland seas masses of living undifferentiated protoplasm. Bessels assigns to these the name of Protobathybius, but they are apparently indistinguishable from the Bathybius of the *Porcupine*. Further arguments against the reality of Bathybius will therefore be needed before a doctrine founded on observations so carefully conducted shall be relegated to the region of confuted hypotheses.

Assuming then, that Bathybius, however much its supposed wide distribution may have been limited by more recent researches, has a real existence, it presents us with a condition of living matter the most rudimental it is possible to conceive. No law of morphology has as yet exerted itself in this formless slime. Even the simplest individualisation is absent. We have a living mass, but we know not where to draw its boundary lines; it is living matter, but we can scarcely call it a living being.

We are not, however, confined to Bathybius for examples of protoplasm in a condition of extreme simplicity. Haeckel has found, inhabiting the fresh waters in the neighbourhood of Jena, minute lumps of protoplasm, which when placed under the microscope were seen to have no constant shape, their outline being in a state of perpetual change, caused by the protrusion from various parts of their surface of broad lobes and thick finger-like projections, which, after remaining visible for a time, would be withdrawn, to make their appearance again on some other part of the surface.

These changeable protrusions of its substance, without fixed position or definite form, are eminently characteristic of protoplasm in some of its simplest conditions. They have been termed "Pseudopodia," and will frequently come before you in what I have yet to say.

To the little protoplasmic lumps thus constituted, Haeckel has given the name of *Protamœba primitiva*. They may be compared to minute detached pieces of Bathybius. He has seen them multiplying themselves by spontaneous division into two pieces, which, on becoming independent, increase in size and acquire all the characters of the parent.

Several other beings as simple as *Protamœba* have been described by various observers, and especially by Haeckel, who brings the whole together into a group to which he gives the name of MONERA, suggested by the extreme simplicity of the beings included in it.

But we must now pass to a stage a little higher in the development of protoplasmic beings. Widely distributed in the fresh and salt waters of Britain, and probably of almost all parts of the world, are small particles of protoplasm closely resembling the *Protamœba* just described. Like it, they have no definite shape, and are perpetually changing their form, throwing out and drawing in thick lobes and finger-like pseudopodia, in which their body seems to flow away over the field of the microscope. They are no longer, however, the homogeneous particle of protoplasm which forms the body of *Protamœba*. Towards the centre a small globular mass of firmer protoplasm has become differentiated off from the remainder, and forms what is known as a nucleus, while the protoplasm forming the extreme outer boundary differs slightly from the rest, being more transparent, destitute of granules, and apparently somewhat firmer han the interior. We may also notice that at one spot a clear spherical space has made its appearance, but that while we watch it has suddenly contracted and vanished, and after a few seconds has begun to dilate so as again to come into view, once more to disappear, then again to return, and all this in regular rhythmical sequence. This little rhythmically pulsating cavity is called the "contractile vacuole." It is of very frequent occurrence among those beings which lie low down in the scale of life.

We have now before us a being which has arrested the attention of naturalists almost from the commencement of microscopical observation. It is the famous *Amœba*, for which ponds and pools and gutters on the house roof have for the last 200 years been ransacked by the microscopist, who has many a time stood in amazement at the undefinable form and Protean changes of this particle of living matter. It is only the science of our own days, however, which has revealed its biological importance, and shown that in this little soft nucleated particle we have a body whose significance for the morphology and physiology of living beings cannot be over estimated, for in *Amœba* we have the essential characters of a CELL, the morphological unit of organisation, the physiological source of specialised function.

The term "cell" has been so long in use that it cannot now be displaced from our terminology; and yet it tends to convey an incorrect notion, suggesting, as it does, the idea of a hollow body or vesicle, this having been the form under which it was first studied. The cell, however, is essentially a definite mass of protoplasm having a nucleus imbedded in it. It may, or may not, assume the form of a vesicle; it may, or may not, be protected by an enveloping membrane; it may, or may not, contain a contractile vacuole; and the nucleus may, or may not, contain within it one or more minute secondary nuclei or "nucleoli."

Haeckel has done good service to biology in insisting on the necessity of distinguishing such non-nucleated forms as are presented by *Protamœba* and the other *Monera* from the nucleated forms as seen in *Amœba*. To the latter he would restrict the word *cell*, while he would assign that of "cytode" to the former.[1]

[1] In every typical cell three parts may be distinguished. There is first the more or less liquid granular protoplasm; secondly the nucleus; and thirdly an external more firm zone of protoplasm, known as the 'cortical layer'—the Hautschicht of the German histologists. All these parts may be regarded as portions differentiated out of the original simple protoplasm. Cells do not, however, always remain on a stage of such simplicity as that presented by *Amœba*. The nucleus is always at its origin quite homogeneous, but as it increases in size it usually manifests a differentiation resulting in a constitution which recent research has shown to be more complex than had been previously supposed; for we often find it to present an external firmer layer, or nuclear membrane, including within it the softer nuclear protoplasm, in which again a network of filaments has been in many instances described.

The structure of the nucleus has been quite recently studied by Flemming (*Arch. f. mikr. Anat.*, Band xvi. Heft 2, 1878), who has given particular attention to this intranuclear network. He maintains that in its completed state the nucleus consists of a parietal firm layer, which incloses, besides specially differentiated nucleoli, a framework (Gerüst) of filaments with a more fluid intervening substance. He further insists on the fact that, with the differentiation of a nucleus, there is introduced a chemical difference between its substance and that of the surrounding cell substance, as shown not only by a different behaviour of the nucleus towards re-agents, but by an actually determined difference of chemical composition.

Klein (*Quarterly Journ. Micr. Sci.* vol. xviii. p. 315) has shown that in the cells of the stomach of *Triton cristatus* there is a delicate intranuclear network of filaments in all respects resembling that described by Flemming; and he further maintains that the network of the nucleus is here continuous, through minute apertures near the poles of the nuclear membrane, with a similar network in the surrounding cell-substance. In this cell-substance he distinguishes two parts—the homogeneous ground substance and the intra-cellular network of filaments.

Flemming, however, will not admit this connection between intra-nuclear and intra-cellular filaments, and Schleicher, as the result of his very recent researches on the division of cartilage-cells ("Die Knorpelzelltheilung," *Arch. f. mikr. Anat.*, Band xvi. Heft 2, 1878), concludes that in these there is no true intra-cellular network, the nucleus being here composed of a multitude of separate rodlets, filaments, and granules surrounded by the nuclear membrane.

The minute granules which are generally seen in the soft protoplasm of the cell do not seem to be essential constituents. They are probably nutritive matter introduced from without, and in process of assimilation and conversion into proper protoplasm. Hanstein has distinguished by the term Metaplasm these granules from the proper homogeneous protoplasm in which they are suspended. The external cortical layer is quite destitute of them: on this devolves the property of protecting the contents from the unfavourable action of outer influences, and to it alone in plants is allocated the property of secreting the cellulose boundary wall.

Several recent observers, but more especially Strasburger ("Studien über das Protoplasma," *Jenaische Zeitschr.*, 1876), have described in the cortical layer of various cells a radial striation, as if formed by excessively delicate rodlets (Stäbchen), placed vertically to the surface and in close proximity to one another. He has seen a relation between these and the cilia on the swarm spores of Vaucheria, where each cilium seems to be supported by a rodlet. That this condition of the cortical layer, however, has not a general feature of cell protoplasm, is certain; it is but a special case of structural differentiation. Indeed, the complex structure which has been detected in the nucleus and in the surrounding cell-protoplasm can scarcely be other-

Let us observe our *Amœba* a little closer. Like all living beings, it must be nourished. It cannot grow as a crystal would grow by accumulating on its surface molecule after molecule of matter. It must *feed.* It must take into its substance the necessary nutriment; it must assimilate this nutriment, and convert it into the material of which it is itself composed.

If we seek, however, for a mouth by which the nutriment can enter into its body, or a stomach by which this nutriment can be digested, we seek in vain. Yet watch it for a moment as it lies in a drop of water beneath our microscope. Some living denizen of the same drop is in its neighbourhood, and its presence exerts on the protoplasm of the *Amœba* a special stimulus which gives rise to the movements necessary for the prehension of nutriment. A stream of protoplasm instantly runs away from the body of the *Amœba* towards the destined prey, envelops it in its current, and then flows back with it to the central protoplasm, where it sinks deeper and deeper into the soft yielding mass, and becomes dissolved, digested, and assimilated in order that it may increase the size and restore the energy of its captor.

But again, like all living things, *Amœba* must multiply itself, and so after attaining a certain size its nucleus divides into two halves, and then the surrounding protoplasm becomes similarly cleft, each half retaining one-half of the original nucleus. The two new nucleated masses which thus arise now lead an independent life, assimilate nutriment, and attain the size and characters of the parent.

We have just seen that in the body of an *Amœba* we have the type of a cell. Now both the fresh waters and the sea contain many living beings beside *Amœba* which never pass beyond the condition of a simple cell. Many of these, instead of emitting the broad lobe-like pseudopodia of *Amœba*, have the faculty of sending out long thin threads of protoplasm, which they can again retract, and by the aid of which they capture their prey or move from place to place. Simple structureless protoplasm as they are, many of them fashion for themselves an outer membranous or calcareous case, often of symmetrical form and elaborate ornamentation, or construct a silicious skeleton of radiating spicula, or crystal clear concentric spheres of exquisite symmetry and beauty.

Some move about by the aid of a flagellum, or long whip-like projection of their bodies, by which they lash the surrounding waters, and which, unlike the pseudopodia of *Amœba*, cannot, during active life, be withdrawn into the general protoplasm of the body; while among many others locomotion is effected by means of cilia—microscopic vibratile hairs, which are distributed in various ways over the surface, and which, like the pseudopodia and flagella, are simple prolongations of their protoplasm.

In every one of these cases the entire body has the morphological value of a cell, and in this simple cell reside the whole of the properties which manifest themselves in the vital phenomena of the organism.

The part fulfilled by these simple unicellular beings in the economy of nature has at all times been very great, and many geological formations, largely built up of their calcareous or silicious skeletons, bear testimony to the multitudes in which they must have swarmed in the waters of the ancient earth.

Those which have thus come down to us from ancient times owe their preservation to the presence of the hard persistent structures secreted by their protoplasm, and must, after all, have formed but a very small proportion of the unicellular organisms which peopled the ancient world, and there fulfilled the duties allotted to them in nature, but whose soft, perishable bodies have left no trace behind.

In our own days similar unicellular organisms are at work, taking their part silently and unobtrusively in the great scheme of creation, and mostly destined, like their predecessors, to leave behind them no record of their existence. The Red Snow Plant, to which is mainly due the beautiful phenomenon by which tracts of Arctic and Alpine snow become tinged of a delicate crimson, is a microscopic organism whose whole body consists of a simple spherical cell. In the protoplasm of this little cell must reside all the essential attributes of life; it must grow by the reception of nutriment; it must repeat by multiplication that form which it has itself inherited from its parent; it must be able to respond to the stimulus of the physical conditions by which it is surrounded. And there it is, with its structure almost on the bounds of extremest simplification, taking its allotted part in the economy of nature, combining into living matter the lifeless elements which lie around it, redeeming from sterility the regions of never-thawing ice, and peopling with its countless millions the wastes of the snow land.[1]

But organisation does not long rest on this low stage of unicellular simplicity, for as we pass from these lowest forms into higher, we find cell added to cell, until many millions of such units become associated in a single organism, where each cell, or each group of cells, has its own special work, while all combine for the welfare and unity of the whole.

In the most complex animals, however, even in man himself, the component cells, notwithstanding their frequent modification and the usual intimacy of their union, are far from losing their individuality. Examine under the microscope a drop of blood freshly taken from the human subject, or from any of the higher animals. It is seen to be composed of a multitude of red corpuscles, swimming in a nearly colourless liquid, and along with these, but in much smaller numbers, somewhat larger colourless corpuscles. The red corpuscles are modified cells, while the colourless corpuscles are cells still retaining their typical form and properties. These last are little masses of protoplasm, each enveloping a central nucleus. Watch them. They will be seen to change their shape; they will project and withdraw pseudopodia, and creep about like an *Amœba*. But, more than this, like an *Amœba*, they will take in solid matter as nutriment. They may be fed with coloured food, which will then be seen to have accumulated in the interior of their soft transparent protoplasm; and in some cases the colourless blood corpuscles have actually been seen to devour their more diminutive companions, the red ones.

Again, there are certain cells filled with peculiar coloured matters, and called pigment cells, which are especially abundant, as constituents of the skin in fishes, frogs, and other low vertebrate, as well as many invertebrate, animals. Under certain stimuli, such as that of light, or of emotion, these pigment cells change their form, protrude or retract pseudopodial prolongations of their protoplasm, and assume the form of stars or of irregularly lobed figures, or again draw themselves together into little globular masses. To this change of form in the pigment cell the rapid change of colour so frequently noticed in the animals provided with them is to be attributed.

The animal egg, which in its young state forms an element in the structure of the parent organism, possesses in the relations now under consideration a peculiar interest. The egg is a true cell, consisting essentially of a lump of protoplasm inclosing a nucleus, and having a nucleolus included in the interior of the nucleus. While still very young it has no constant form and is perpetually changing its shape. Indeed, it is often impossible to distinguish it from an *Amœba;* and it may, like an *Amœba*, wander from place to place by the aid of its pseudopodial projections. I have shown elsewhere[2] that the primitive egg of the remarkable hydroid *Myriothela*, manifests amœboid motions; while Haeckel has shown[3] that in the sponges certain *Amœba*-like organisms, which are seen wandering about in the various canals and cavities of their bodies, and had been until lately regarded as parasites which had gained access from without, are really the eggs of the sponge; and a similar amœboid condition is presented by the very young eggs of even the highest animals.

Again, Reichenbach has proved[4] that during the development of the crayfish the cells of the embryo throw out pseudopodia by which, exactly as in an *Amœba*, the yolk spheres which serve as nutriment for the embryo are surrounded and engulphed in the protoplasm of the cells.

I had shown some years ago[5] that in *Myriothela*, pseudopodial processes are being constantly projected from the walls of the alimentary canal into its cavity. They appear as direct extensions of a layer of clear, soft, homogeneous protoplasm which lies over the surface of the naked cells lining the cavity, and which I now regard as the "Hautschicht" or cortical layer of these cells. I then suggested that the function of these

wise regarded than as an expression of an early differentiation in the structure of the cell, and not, as has been maintained, an ultimate or "plastidular" ondition of protoplasm

[1] The Red Snow Plant (*Protococcus nivalis*) acts on the atmosphere through the agency of chlorophyll, like the ordinary green plants. As in these, chlorophyll is developed in it, and is only withdrawn from view by the predominant red pigment to which the *Protococcus* owes one of its most striking characteristics.

[3] *Jenaische Zeitschr.*, 1871.

[4] "Die Embryonanlage und erste Entwickelung des Flusskrebse," *Zeitschr. f. wissens. Zoologie*, 1877.

[5] *Loc. cit.*

pseudopodia lay in seizing, in the manner of an *Amœba*, such alimentary matter as may be found in the contents of the canal, and applying it to the nutrition of the hydroid.

What I had thus suggested with regard to *Myriothela* has been since proved in certain planarian worms by Metschnikoff,[1] who has seen the cells which line the alimentary canal in these animals act like independent *Amœbæ*, and engulph in their protoplasm such solid nutriment as may be contained in the canal. When the planaria was fed with colouring matter these amœboid cells became gorged with the coloured particles just as would have happened in an *Amœba* when similarly fed.

But it is not alone in such loosely aggregated cells as those of the blood, or in the amœboid cells of the alimentary canal, or in such scattered constituents of the tissues as the pigment cells, or in cells destined for an ultimate state of freedom, as the egg, that there exists an independence. The whole complex organism is a society of cells, in which every individual cell possesses an independence, an autonomy, not at once so obvious as in the blood cells, but not the less real. With this autonomy of each element there is at the same time a subordination of each to the whole, thus establishing a unity in the entire organism, and a concert and harmony between all the phenomena of its life.

In this society of cells each has its own work to perform, and the life of the organism is made up of the lives of its component cells. Here it is that we find most distinctly expressed the great law of the physiological division of labour. In the lowest organisms, where the whole being consists of a single cell, the performance of all the processes which constitute its life must devolve on the protoplasm of this one cell; but as we pass to more highly organised beings, the work becomes distributed among a multitude of workers. These workers are the cells which now make up the complex organism. The distribution of labour, however, is not a uniform one, and we are not to suppose that the work performed by each cell is but a repetition of that of every other. For the life processes, which are accumulated in the single cell of the unicellular organism become in the more complex organism differentiated, some being intensified and otherwise modified and allocated to special cells, or to special groups of cells, which we call organs, and whose proper duty is now to take charge of the special processes which have been assigned to them. In all this we have a true division of labour —a division of labour, however, by no means absolute; for the processes which are essential to the life of the cell must still continue common to all the cells of the organism. No cell, however great may be the differentiation of function in the organism, can dispense with its irritability, the one constant and essential property of every living cell. There thus devolves on each cell or group of cells some special work which contributes to the well-being of all, and their combined labours secure the necessary conditions of life for every cell in the community, and result in those complex and wonderful phenomena which constitute the life of the higher organisms.

We have hitherto considered the cell only as a mass of active nucleated protoplasm, either absolutely naked, or partially inclosed in a protective case, which still permits free contact of the protoplasm with the surrounding medium. In very many instances, however, the protoplasm becomes confined within resisting walls, which entirely shut it in from all direct contact with the medium which surrounds it. With the plant this is almost always so after the earliest stages of its life. Here the protoplasm of the cells is endowed with the faculty of secreting over its surface a firm, resisting membrane, composed of cellulose, a substance destitute of nitrogen, thus totally different from the contained protoplasm, and incapable of manifesting any of the phenomena of life.

Within the walls of cellulose the protoplasm is now closely imprisoned, but we are not on that account to suppose that it has lost its activity, or has abandoned its work as a living being. Though it is now no longer in direct contact with the surrounding medium, it is not the less dependent on it, and the reaction between the imprisoned protoplasm and the outer world is still permitted by the permeability of the surrounding wall of cellulose.

When the protoplasm thus becomes surrounded by a cellulose wall it seldom retains the uniform arrangement of its parts which is often found in the naked cells. Minute cavities or vacuoles make their appearance in it; these increase in size and run one into the other, and may finally form one large cavity in the centre, which becomes filled with a watery fluid, known as the Cell Sap. This condition of the cell was the first observed, and it was it which suggested the often inapplicable term "cell." By the formation of this central sap cavity the surrounding protoplasm is pushed aside, and pressed against the cellulose wall, over which it now extends as a continuous layer. The nucleus either continues near the centre, enveloped by a layer of protoplasm, which is connected by radiating bands of protoplasm with that of the walls, or it accompanies the displaced protoplasm, and lies embedded in this on the walls of the cell.

We have abundant evidence to show that the imprisoned protoplasm loses none of its activity. The *Characeæ* constitute an exceedingly interesting group of simple plants, common in the clear water of ponds and of slowly-running streams. The cells of which they are built up are comparatively large, and, like almost all vegetable cells, are each inclosed in a wall of cellulose. The cellulose is perfectly transparent, and if the microscope, even with a low power, be brought to bear on one of these cells, a portion of its protoplasm may be seen in active rotation, flowing up one side of the long tubular cell and down the other, and sweeping on with it such more solid particles as may become enveloped in its current. In another water plant, the *Valisneria spiralis*, a similar active rotation of the protoplasm may be seen in the cells of the leaf, where the continuous stream of liquid protoplasm sweeping along the green granules of chlorophyll, and even carrying the globular nucleus with it in its current, presents one of the most beautiful of the many beautiful phenomena which the microscope has revealed to us.

In many other cells with large sap cavities, such as those which form the stinging hairs of nettles and other kinds of vegetable hairs, the protoplasmic lining of the wall may send off into the sap cavity projecting ridges and strings, forming an irregular network, along which, under a high power of the microscope, a slow streaming of granules may be witnessed. The form and position of this protoplasmic network undergo constant changes, and the analogy with the changes of form in an *Amœba* becomes obvious. The external wall of cellulose renders it impossible for the confined protoplasm to emit, like a naked *Amœba*, pseudopodia from its outer side; but on the inner side there is no obstacle to the extension of the protoplasm, and here the cavity of the cell becomes more or less completely traversed by protoplasmic projections from the wall. These often stretch themselves out in the form of thin filaments, which, meeting with a neighbouring one, become fused into it; they show currents of granules streaming along their length, and after a time become withdrawn and disappear. The vegetable cell, in short, with its surrounding wall of cellulose, is in all essential points a closely imprisoned Rhizopod.

Further proof that the imprisoned protoplasm has lost by its imprisonment none of its essential irritability, is afforded by the fact that if the transparent cell of a Nitella, one of the simple water plants just referred to, be touched under the microscope with the point of a blunt needle, its green protoplasm will be seen to recede, under the irritation of the needle, from the cellulose wall. If the cellulose wall of the comparatively large cell which forms the entire plant in a Vaucheria, a unicellular alga, very common in shallow ditches, be ruptured under the microscope, its protoplasm will escape, and may then be often seen to throw out pseudopodial projections and exhibit amœboid movements.

Even in the higher plants, without adducing such obvious and well-known instances as those of the Sensitive Plant and Venus's Flytrap, the irritability of the protoplasm may be easily rendered manifest. There are many herbaceous plants in which if the young succulent stem of a vigorously growing specimen receive a sharp blow, of such a nature, however, as not to bruise its tissues, or in any way wound it, the blow will sometimes be immediately followed by a drooping of the stem commencing at some distance above the point to which the stroke had been applied; its strength appears to have here suddenly left it, it is no longer able to bear its own weight, and seems to be dying. The protoplasm, however, of its cells, is in this instance not killed, it is only stunned by the violence of the blow, and needs time for its restoration. After remaining, it may be for some hours, in this drooping and flaccid state, the stem begins to raise itself, and soon regains its original vigour. This experiment will generally succeed well in plants with a rather large terminal spike or raceme when the stroke is applied some little distance below the inflorescence shortly before the expansion of the flower.

[1] "Ueber die Verdauungsorgane einiger Süsswasser-Turbellarien," *Zoologischer Anzeiger*, December, 1878.

In the several instances now adduced the protoplasm is in the mature state of the plant entirely included within a wall of cellulose. Some recent beautiful observations, however, of Mr. Francis Darwin have shown that even in the higher plants truly naked protoplasm may occur. From the cells of certain glandular hairs contained within the cup-like receptacles formed by the united bases of two opposite leaves in the Teazel (*Dipsacus*) he has seen emitted long pseudopodia-like projections of the protoplasm. What may be the significance of this very exceptional phenomenon is still undetermined. It is probably as Mr. Darwin supposes connected with the absorption of nitrogenous matter.

That there is no essential difference between the protoplasm of plants and that of animals is rendered further evident by other motor phenomena, which we are in the habit of regarding as the exclusive attribute of animals. Many of the more simply organised plants give origin to peculiar cells called spores, which separate from the parent, and, like the seeds of the higher plants, are destined to repeat its form. In many cases these spores are eminently locomotive. They are then termed "swarm-spores," and their movements are brought about, sometimes by changes of shape, when they move about in the manner of an *Amœba*, but more frequently by minute vibratile cilia, or by more strongly developed flagella or whip-like projections of their protoplasm. These cilia and flagella are absolutely indistinguishable from similar structures widely distributed among animals, and by their vibratory or lashing strokes upon the surrounding water the swarm-spores are rapidly carried from place to place. In these motions they often present a curious semblance of volition, for if the swarm-spore meet with an obstacle in its course, it will, as if to avoid it, change the direction of its motion, and retreat by a reversion of the stroke of its cilia. They are usually attracted by light, and congregate at the light side of the vessel which contains them, though in some cases light has the opposite effect on them, and they recede from it.

Another fact may here be adduced to show the uniform character of protoplasm and how very different are its properties from those of lifeless matter, namely, the faculty which all living protoplasm possesses of resisting the entrance of colouring matter into its substance. As many here present are aware, microscopists are in the habit of using in their investigations various colouring matters, such as solutions of carmine. These act differently on the different tissues, staining some, for example, more deeply than others, and thus enabling the histologist to detect certain elements of structure, which would otherwise remain unknown. Now if a solution of carmine be brought into contact with living protoplasm, this will remain, so long as it continues alive, unaffected by the colouring matter. But if the protoplasm be killed, the carmine will at once pervade its whole substance, and stain it throughout with a colour more intense than even that of the colouring solution itself.

But no more illustrative example can be offered of the properties of protoplasm as living matter, independently of any part it may take in organisation, than that presented by the Myxomycetæ.

The Myxomycetæ constitute a group of remarkable organisms, which, from their comparatively large size and their consisting, during a great part of their lives, of naked protoplasm, have afforded a fine field for research, and have become one of the chief sources from which our knowledge of the nature and phenomena of protoplasm has been derived.

They have generally been associated by botanists with the fungi, but though their affinities with these are perhaps closer than with any other plants, they differ from them in so many points, especially in their development, as to render this association untenable. They are found in moist situations, growing on old tan or on moss, or decaying leaves or rotten wood, over which they spread in the form of a network of naked protoplasmic filaments, of a soft creamy consistence, and usually of a yellowish colour.

Under the microscope the filaments of the network exhibit active spontaneous movements, which, in the larger branches, are visible under an ordinary lens, or even by the naked eye. A succession of undulations may then be noticed passing along the course of the threads. Under higher magnifying powers a constant movement of granules may be seen flowing along the threads, and streaming from branch to branch of this wonderful network. Here and there off-shoots of the protoplasm are projected, and again withdrawn in the manner of the pseudopodia of an *Amœba*, while the whole organism may be occasionally seen to abandon the support over which it had grown, and to creep over neighbouring surfaces, thus far resembling in all respects a colossal ramified *Amœba*. It is also curiously sensitive to light, and may be sometimes found to have retreated during the day to the dark side of the leaves, or into the recesses of the tan over which it had been growing, and again to creep out on the approach of night.

After a time there arise from the surface of this protoplasmic net oval capsules or spore cases, in which are contained the spores or reproductive bodies of the Myxomycetæ. When the spore-case has arrived at maturity, it bursts and allows the spores to escape. These are in the form of spherical cells, each included in a delicate membranous wall, and when they fall into water the wall becomes ruptured, and the little cell creeps out. This consists of a little mass of protoplasm with a round central nucleus, inclosing a nucleolus, and with a clear vacuole, which exhibits a rhythmically pulsating movement. The little naked spore thus set at liberty is soon seen to be drawn out at one point into a long vibratile whip-like flagellum, which by its lashing action carries the spore from place to place. After a time the flagellum disappears, and the spore may now be seen emitting and withdrawing finger-like pseudopodia, by means of which it creeps about like an *Amœba*, and like an *Amœba* devours solid particles by engulfing them in its soft protoplasm.

So far these young *Amœba*-like Myxomycetæ have enjoyed each an independent existence. Now, however, a singular and significant phenomenon is presented. Two or more of these Myxamœbæ, as they have been called, approach one another, come into contact, and finally become completely fused together into a single mass of protoplasm, in which the components are no longer to be distinguished. To the body thus formed by the fusion of the Myxamœbæ the name of "plasmodium" has been given.

The plasmodium continues, like the simple amœbiform bodies of which it is composed, to grow by the ingestion and assimilation of solid nutriment, which it envelopes in its substance; it throws out ramifying and mosculating processes, and finally becomes converted into a protoplasmic network, which in its turn gives rise to spore-cases with their contained spores, and thus completes the cycle of its development.

Under certain external conditions, the Myxomycetæ have been observed to pass from an active mobile state into a resting state, and this may occur both in the amœbiform spores and in the plasmodium. When the plasmodium is about to pass into a resting state, it usually withdraws its finer branches, and expels such solid ingesta as may be included in it. Its motions then gradually cease, it breaks up into a multitude of polyhedral cells, which, however, remain connected, and the whole body dries into a horny brittle mass, known by the name of "sclerotium."

In this condition, without giving the slightest sign of life, the sclerotium may remain for many months. Life, however, is not destroyed, its manifestations are only suspended, and if after an indefinite time the apparently dead sclerotium be placed in water, it immediately begins to swell up, the membranous covering of its component cells becomes dissolved and disappears, and the cells themselves flow together into an active amœboid plasmodium.

We have already seen that every cell posseses an autonomy or independent individuality, and from this we should expect that, like all living beings it had the faculty of multiplying itself, and of becoming the parent of other cells. This is truly the case, and the process of cell-multiplication has of late years been studied, with the result of adding largely to our knowledge of the phenomena of life.

The labours of Strasburger, of Auerbach, of Oscar Hertwig, of Eduard van Beneden, Bütschli, Fol, and others, here come prominently before us, but neither the time at my disposal nor the purport of this address will allow me to do more than call your attention to some of the more striking results of their investigations.

By far the most frequent mode of multiplication among cells shows itself in a spontaneous division of the protoplasm into two separate portions, which then become independent of one another, so that instead of the single parent cell two new ones have made their appearance. In this process the nucleus usually takes an important part. Strasburger has studied it with great care in certain plant cells, such as the so-called "corpuscula" or "secondary embryo-sacs" of the Coniferæ and the cells of Spirogyra; and has further shown a close correspondence between cell division in animals and that in plants.

It may be generally stated as the results of his observations on the corpuscula of the Coniferæ, that the nucleus of the cell about to divide assumes a spindle shape, and at the same time presents a peculiar striated differentiation, as if it were composed of parallel filaments reaching from end to end of the spindle. These filaments become thickened in the middle, and there form by the approximation of the thickened portions a transverse plate of protoplasm (the "nucleus-plate"). This soon splits into two halves, which recede from one another towards the poles of the spindle, travelling in this course along the filaments, which remain continuous from end to end. When arrived near the poles they form there two new nuclei, still connected with one another by the intervening portion of the spindle.

In the equator of this intervening portion there is now formed in a similar way a second plate of protoplasm (the "cell-plate"), which, extending to the walls of the dividing cell, cuts the whole protoplasm into two halves, each half containing one of the newly-formed nuclei. This partition plate is at first single, but it soon splits into two laminæ, which become the apposed bounding surfaces of the two protoplasm masses into which the mother cell has been divided. A wall of cellulose is then all at once secerted between them, and the two daughter cells are complete.

It sometimes happens in the generation of cells that a young brood of cells arises from the parent cell by what is called "free cell formation." In this only a part of the protoplasm of the mother cell is used up in the production of the offspring. It is seen chiefly in the formation of the spores of the lower plants, in the first foundation of the embryo in the higher, and in the formation of the endosperm—a cellular mass which serves as the first nutriment for the embryo—in the seeds of most Phanerogams. The formation of the endosperm has been carefully studied by Strasburger in the embyro-sac of the kidney bean, and may serve as an example of the process of free cell formation. The embryo-sac is morphologically a large cell with its protoplasm, nucleus, and cellulose wall, while the endosperm which arises within it is composed of a multitude of minute cells united into a tissue. The formation of the endosperm is preceded by the dissolution and disappearance of the nucleus of the embryo-sac, and then in the midst of the protoplasm of the sac several new nuclei make their appearance. Around each of these as a centre the protoplasm of the mother cell is seen to have become differentiated in the form of a clear spherule, and we have thus corresponding to each of the new nuclei a young naked cell, which soon secretes over its surface a membrane of cellulose. The new cells, when once formed, multiply by division, press one on the other, and so combining into a cellular mass, constitute the completed endosperm.

Related to the formation of new cells, whether by division or by free cell formation, is another very interesting phenomenon of living protoplasm known as "rejuvenescence." In this the whole protoplasm of a cell, by a new arrangement of its parts, assumes a new shape and acquires new properties. It then abandons its cellulose chamber, and enters on a new and independent life in the surrounding medium.

A good example of this is afforded by the formation of swarm-spores in Œdogonium, one of the fresh-water algæ. Here the whole of the protoplasm of an adult cell contracts, and by the expulsion of its cell-sap changes from a cylindrical to a globular shape. Then one spot becomes clear, and a pencil of vibratile cilia here shows itself. The cellulose wall which had hitherto confined it now becomes ruptured, and the protoplasmic sphere, endowed with new faculties of development and with powers of active locomotion, escapes as a swarm-spore, which, after enjoying for a time the free life of an animal, comes to rest, and develops itself into a new plant.

The beautiful researches which have within the last few years been made by the observers already mentioned, on the division of animal cells, show how close is the agreement between plants and animals in all the leading phenomena of cell division, and afford one more proof of the essential unity of the two great organic kingdoms.

There is one form of cell which, in its relation to the organic world, possesses a significance beyond that of every other, namely, the egg. As already stated, the egg is, wherever it occurs, a typical cell, consisting essentially of a globule of protoplasm enveloping a nucleus (the "germinal vesicle"), and with one or more nucleoli (the "germinal spots") in the interior of the nucleus. This cell, distinguishable by no tangible characters from thousands of other cells, is nevertheless destined to run through a definite series of developmental changes, which have as their end the building up of an organism like that to which the egg owes its origin.

It is obvious that such complex organisms as thus result—composed, it may be, of countless millions of cells—can be derived from the simple egg cell only by a process of cell multiplication. The birth of new cells derived from the primary cell or egg thus lies as the basis of embryonic development. It is here that the phenomena of cell multiplication in the animal kingdom can in general be most satisfactorily observed, and the greater number of recent researches into the nature of these phenomena have found their most fertile field in the early periods of the development of the egg.

A discussion of the still earlier changes which the egg undergoes in order to bring it into the condition in which cell multiplication may be possible, would, however full of interest, be here out of place; and I shall therefore confine myself to the first moments of actual development—to what is called "the cleavage of the egg"—which is nothing more than a multiplication of the egg cell by repeated division. I shall further confine myself to an account of this phenomenon as presented in typical cases, leaving out of consideration certain modifications which would only complicate and obscure our picture.

The egg, notwithstanding the preliminary changes to which I have alluded, is still at the commencement of development, a true cell. It has its protoplasm and its nucleus, and it is, as a rule, enveloped in a delicate membrane. The protoplasm forms what is known as the vitellus, or yolk, and the surrounding membrane is callled the "vitellary membrane." The division which is now about to take place in it is introduced by a change of form in the nucleus. This becomes elongated, and assumes the shape of a spindle, similar to what we have already seen in the cell-division of plants. On each pole of the spindle transparent protoplasm collects, forming here a clear spherical area.

At this time a very striking and characteristic phenomenon is witnessed in the egg. Each pole of the spindle has become the centre of a system of rays which stream out in all directions into the surrounding protoplasm. The protoplasm thus shows, enveloped in its mass, two sun-like figures, whose centres are connected to one another by the spindle-shaped nucleus. To this, with the sun-like rays streaming from its poles, Auerbach gives the name of "Karyolitic figure," suggested by its connection with the breaking up of the original nucleus, to which our attention must next be directed.

A phenomenon similar to one we have already seen in cell-division among plants now shows itself. The nucleus becomes broken up into a number of filaments, which lie together in a bundle, each filament stretching from pole to pole of the spindle. Exactly in its central point every filament shows a knot-like enlargement, and from the close approximation of the knots there results a thick zone of protoplasm in the equator of the spindle. Each knot soon divides into two halves, and each half recedes from the equator and travels along the filament towards its extremity. When arrived at the poles of the spindle each set of half knots becomes fused together into a globular body, while the intervening portion of the spindle, becoming torn up, and gradually drawn into the substance of the two globular masses, finally disappears. And now, instead of the single fusiform nucleus whose changes we have been tracing, we have two new globular nuclei, each occupying the place of one of its poles, and formed at its expense.[1] The egg now begins to divide along

[1] Though none of the above-mentioned observers to whom we owe our knowledge of the phenomena here described seem to have thought of connecting the fibrous condition assumed by the spindle with any special structure of the quiescent nucleus, it is highly probable that it consists in a rearrangement of fibres already present. That this is really the case is borne out by the observations of Schleicher on the division of cartilage cells. ("Die Knorpelzelltheilung," *Arch. für mikr. Anat.*, Band xvi. Heft 2, 1878.) From these it would appear that in the division of cartilage cells the investing membrane of the nucleus first becomes torn up, and then the filaments, rodlets, and granules, which, according to him, form its body, enter into a state of intense motor activity, and may be seen arranging themselves into star-like, or wreath-like, or irregular figures, while the whole nucleus, now deprived of its membrane, may wander about the cell, travelling towards one of its poles, and then towards the other; or it may at one time contract, and then again dilate, to such an extent as nearly to fill the entire cell. To this nuclear activity Schleicher applies the term "Karyokinesis." It results in a nearly parallel arrangement of the nuclear filaments. Then these converge at their extremities and become more widely separated in the middle, so as to give to the nucleus the form of a spindle. The filaments then become fused together at each pole of the spindle, so as to form the two new nuclei, which are at first nearly homogeneous, but which afterwards become broken up into their component filaments, rods, and granules.

a plane at right angles to a line connecting the two nuclei. The division takes place without the formation of a cell plate such as we saw in the division of the plant cell, and is introduced by a constriction of its protoplasm, which commences at the circumference just within the vitelline membrane, and extending towards the centre, divides the whole mass of protoplasm into two halves, each including within it one of the new nuclei. Thus the simple cell which constituted the condition of the egg at the commencement of development becomes divided into two similar cells. This forms the first stage of cleavage. Each of these two young cells divides in its turn in a direction at right angles to the first division-plane, while by continued repetition of the same act the whole of the protoplasm or yolk becomes broken up into a vast multitude of cells, and the unicellular organism—the egg, with which we began our history—has become converted into an organism composed of many thousands of cells. This is one of the most widely distributed phenomena of the organic world. It is called "the cleavage of the egg," and consists essentially in the production, by division, of successive broods of cells from a single ancestral cell—the egg.

It is no part of my purpose to carry on the phenomena of development further than this. Such of my hearers as may desire to become acquainted with the further history of the embryo, I would refer to the excellent address delivered two years ago at the Plymouth meeting of the Association by one of my predecessors in this chair—Prof. Allen Thompson.

That protoplasm, however, may present a phenomenon the reverse of that in which a simple cell becomes multiplied into many, is shown by a phenomenon already referred to—the production of plasmodia in the Myxomycetæ by the fusion into one another of cells originally distinct.

The genus *Myriothela* will afford another example in which the formation of plasmodia becomes introduced into the cycle of development. The primitive eggs are here, as elsewhere, true cells with nucleolated nuclei, but without any boundary membrane. They are formed in considerable numbers, but remain only for a short time separate and distinct. After this they begin to exhibit amœboid changes of shape, project pseudopodial prolongations which coalesce with those of others in their vicinity, and finally a multitude of these primitive ova become fused together into a common plasmodium, in which, as in the simple egg cell of other animals, the phenomena of development take place.

In many of the lower plants a very similar coalescence is known to take place between the protoplasmic bodies of separate cells, and constitutes the phenomenon of conjugation. *Spirogyra* is a genus of Algæ, consisting of long green threads common in ponds. Every thread is composed of a series of cylindrical chambers of transparent cellulose placed end to end, each containing a sac of protoplasm with a large quantity of cell sap, and with a green band of chlorophyll wound spirally on its walls. When the threads have attained their full growth they approach one another in pairs, and lie in close proximity, parallel one to the other. A communication is then established by means of short connecting tubes between the chambers of adjacent filaments, and across the channel thus formed the whole of the protoplasm of one of the conjugating chambers passes into the cavity of the other, and then immediately fuses with the protoplasm it finds there. The single mass thus formed shapes itself into a solid oval body, known as a "zygospore." This now frees itself from the filament, secretes over its naked surface a new wall of cellulose, and, when placed in the conditions necessary for its development, attaches itself by one end, and then, by repeated acts of cell division, grows into a many-celled filament like those in which it originated.

The formation of plasmodia, regarded as a coalescence and absolute fusion into one another of separate naked masses of protoplasm, is a phenomenon of great significance. It is highly probable that, notwithstanding the complete loss of individuality in the combining elements, such differences as may have been present in these will always find itself expressed in the properties of the resulting plasmodia—a fact of great importance in its bearing on the phenomena of inheritance. Recent researches, indeed, render it almost certain that fertilisation, whether in the animal or the vegetable kingdom, consists essentially in the coalescence and consequent loss of individuality of the protoplasmic contents of two cells.

In by far the greater number of plants the protoplasm of most of the cells which are exposed to the sunlight undergoes a curious and important differentiation, part of it becoming separated from the remainder in the form usually of green granules, known as chlorophyll granules. The chlorophyll granules thus consist of true protoplasm, their colour being due to the presence of a green colouring matter, which may be extracted, leaving behind the colourless protoplasmic base.

The colouring matter of chlorophyll presents under the spectroscope a very characteristic spectrum. For our knowledge of its optical properties, on which time will not now permit me to dwell, we are mainly indebted to the researches of your townsman, Dr. Sorby, who has made these the subject of a series of elaborate investigations, which have contributed largely to the advancement of an important department of physical science.

That the chlorophyll is a living substance, like the uncoloured protoplasm of the cell, is sufficiently obvious. When once formed, the chlorophyll granule may grow by intussusception of nutriment to many times its original size, and may multiply itself by division.

To the presence of chlorophyll is due one of the most striking aspects of external nature—the green colour of the vegetation which clothes the surface of the earth; and with its formation is introduced a function of fundamental importance in the economy of plants, for it is on the cells which contain this substance that devolves the faculty of decomposing carbonic acid. On this depends the assimilation of plants, a process which becomes manifest externally by the exhalation of oxygen. Now it is under the influence of light on the chlorophyll-containing cells that this evolution of oxygen is brought about. The recent observations of Draper and of Pfeffer have shown that in this action the solar spectrum is not equally effective in all its parts; that the yellow and least refrangible rays are those which act with most intensity; that the violet and other highly refrangible rays of the visible spectrum take but a very subordinate part in assimilation; and that the invisible rays which lie beyond the violet are totally inoperative.

In almost every grain of chlorophyll one or more starch granules may be seen. This starch is chemically isomeric with the cellulose cell wall, with woody fibre, and other hard parts of plants, and is one of the most important products of assimilation. When plants whose chlorophyll contains starch are left for a sufficient time in darkness, the starch is absorbed and completely disappears; but when they are restored to the light the starch reappears in the chlorophyll of the cells.

With this dependence of assimilation on the presence of chlorophyll a new physiological division of labour is introduced into the life of plants. In the higher plants, while the work of assimilation is allocated to the chlorophyll-containing cells, that of cell division and growth devolves on another set of cells, which, lying deeper in the plant, are removed from the direct action of light, and in which chlorophyll is therefore never produced. In certain lower plants, in consequence of their simplicity of structure and the fact that all the cells are equally exposed to the influence of light, this physiological division of labour shows itself in a somewhat different fashion. Thus in some of the simple green algæ, such as *Spirogyra* and *Hydrodictyon*, assimilation takes place as in other cases during the day, while their cell division and growth takes place chiefly, if not exclusively, at night. Strasburger, in his remarkable observations on cell divisions in *Spirogyra*, was obliged to adopt an artificial device in order to compel the *Spirogyra* to postpone the division of its cells to the morning.

Here the functions of assimilation and growth devolve on one and the same cell, but while one of these functions is exercised only during the day, the time for the other is the night. It seems impossible for the same cell at the same time to exercise both functions, and these are here accordingly divided between different periods of the twenty-four hours.

The action of chlorophyll in bringing about the decomposition of carbonic acid is not, as was recently believed, absolutely confined to plants. In some of the lower animals, such as *Stentor* and other infusoria, the Green Hydra, and certain green planariæ and other worms, chlorophyll is differentiated in their protoplasm, and probably always acts here under the influence of light exactly as in plants.

Indeed, it has been proved[1] by some recent researches of Mr. Geddes, that the green planarias when placed in water and exposed to the sunlight give out bubbles of gas which contain from 44 to 55 per cent. of oxygen. Mr. Geddes has further shown that these animals contain granules of starch in their tissues, and

[1] "Sur la Fonction de la Chlorophyll dans les Planaires vertes," *Comptes Rendus*, December, 1878.

in this fact we have another striking point of resemblance between them and plants.

A similar approximation of the two organic kingdoms has been shown by the beautiful researches of Mr. Darwin—confirmed and extended by his son, Mr. Francis Darwin—on Drosera and other so-called carnivorous plants. These researches, as is now well known, have shown that in all carnivorous plants there is a mechanism fitted for the capture of living prey, and that the animal matter of the prey is absorbed by the plant after having been digested by a secretion which acts like the gastric juice of animals.

Again, Nägeli has recently shown [1] that the cell of the yeast fungus contains about 2 per cent. of peptine, a substance hitherto known only as a product of the digestion of azotised matter by animals.

Indeed, all recent research has been bringing out in a more and more decisive manner the fact that there is no dualism in life,—that the life of the animal and the life of the plant are, like their protoplasm, in all essential points identical.

But there is, perhaps, nothing which shows more strikingly the identity of the protoplasm in plants and animals, and the absence of any deep-pervading difference between the life of the animal and that of the plant, than the fact that plants may be placed, just like animals, under the influence of anæsthetics.

When the vapour of chloroform or of ether is inhaled by the human subject, it passes into the lungs, where it is absorbed by the blood, and thence carried by the circulation to all the tissues of the body. The first to be affected by it is the delicate nervous element of the brain, and loss of consciousness is the result. If the action of the anæsthetic be continued, all the other tissues are in their turn attacked by it and their irritability arrested. A set of phenomena entirely parallel to these may be presented by plants.

We owe to Claude Bernard a series of interesting and most instructive experiments on the action of ether and chloroform on plants. He exposed to the vapour of ether a healthy and vigorous sensitive plant, by confining it under a bell-glass into which he introduced a sponge filled with ether. At the end of half an hour the plant was in a state of anæsthesia, all its leaflets remained fully extended, but they showed no tendency to shrink when touched. It was then withdrawn from the influence of the ether, when it gradually recovered its irritability, and finally responded, as before, to the touch.

It is obvious that the irritability of the protoplasm was here arrested by the anæsthetic, so that the plant became unable to give a response to the action of an external stimulus.

It is not, however, the irritability of the protoplasm of only the motor elements of plants that anæsthetics are capable of arresting. These may act also on the protoplasm of those cells whose function lies in chemical synthesis, such as is manifestsd in the phenomena of the germination of the seed and in nutrition generally, and Claude Bernard has shown that germination is suspended by the action of ether or chloroform.

Seeds of cress, a plant whose germination is very rapid, were placed in conditions favourable to a speedy germination, and while thus placed were exposed to the vapour of ether. The germination, which would otherwise have shown itself by the next day, was arrested. For five or six days the seeds were kept under the influence of the ether, and showed during this time no disposition to germinate. They were not killed, however, they only slept, for on the substitution of common air for the etherised air with which they had been surrounded, germination at once set in and proceeded with activity.

Experiments were also made on that function of plants by which they absorb carbonic acid and exhale oxygen, and which, as we have already seen, is carried on through the agency of the green protoplasm or chlorophyll, under the influence of light—a function which is commonly, but erroneously, called the respiration of plants.

Aquatic plants afford the most convenient subjects for such experiments. If one of these be placed in a jar of water holding ether or chloroform in solution, and a bell-glass be placed over the submerged plant, we shall find that the plant no longer absorbs carbonic acid or emits oxygen. It remains, however, quite green and healthy. In order to awaken the plant, it is only necessary to place it in non-etherised water, when it will begin once more to absorb carbonic acid, and exhale oxygen under the influence of sunlight.

[1] "Ueber die chemische Zusammensetzung der Hefe," *Sitzungsbericht der math. phys. Classe der k.k. Akad. der Wissens. zu München*, 1878.

The same great physiologist has also investigated the action of anæsthetics on fermentation. It is well known that alcoholic fermentation is due to the presence of a minute fungus, the yeast fungus, the living protoplasm of whose cells has the property of separating solutions of sugar into alcohol, which remains in the liquid, and carbonic acid, which escapes into the air.

Now, if the yeast plant be placed along with sugar in etherised water it will no longer act as a ferment. It is anæsthesiated, and cannot respond to the stimulus which, under ordinary circumstances, it would find in the presence of the sugar. If, now, it be placed on a filter, and the ether washed completely away, it will, on restoration to a saccharine liquid, soon resume its duty of separating the sugar into alcohol and carbonic acid.

Claude Bernard has further called attention to a very significant fact which is observable in this experiment. While the proper alcoholic fermentation is entirely arrested by the etherisation of the yeast plant, there still goes on in the saccharine solution a curious chemical change, the cane sugar of the solution being converted into grape sugar, a substance identical in its chemical composition with the cane sugar, but different in its molecular constitution. Now it is well known from the researches of Bertholet that this conversion of cane sugar into grape sugar is due to a peculiar inversive ferment, which, while it accompanies the living yeast plant, is itself soluble and destitute of life. Indeed it has been shown that in its natural conditions the yeast fungus is unable of itself to assimilate cane sugar, and that in order that this may be brought into a state fitted for the nutrition of the fungus, it must be first digested and converted into grape sugar, exactly as happens in our own digestive organs. To quote Claude Bernard's graphic account:—

"The fungus ferment has thus beside it in the same yeast a sort of servant given by nature to effect this digestion. The servant is the unorganised inversive ferment. This ferment is soluble, and as it is not a plant, but an unorganised body destitute of sensibility, it has not gone to sleep under the action of the ether, and thus continues to fulfil its task."

In the experiment already recorded on the germination of seeds the interest is by no means confined to that which attaches itself to the arrest of the organising functions of the seed, those namely which manifest themselves in the development of the radicle and plumule and other organs of the young plant. Another phenomenon of great significance becomes at the same time apparent—the anæsthetic exerts no action on the concomitant chemical phenomena which in germinating seeds show themselves in the transformation of starch into sugar under the influence of diastase (a soluble and non-living ferment which also exists in the seed), and the absorption of oxygen with the exhalation of carbonic acid. These go on as usual, the anæsthesiated seed continuing to respire, as proved by the accumulation of carbonic acid in the surrounding air. The presence of the carbonic acid was rendered evident by placing in the same vessel with the seeds which were the object of the experiment, a solution of barytes, when the carbonate became precipitated from the solution in quantity equal to that produced in a similar experiment with seeds germinating in unetherised air.

So, also in the experiment which proves the faculty possessed by the chlorophyllian cells of absorbing carbonic acid and exhaling oxygen under the influence of light may be arrested by anæsthetics, it could be seen that the plant, while in a state of anæsthesia, continued to respire in the manner of animals; that is, it continued to absorb oxygen and exhale carbonic acid. This is the true respiratory function which was previously masked by the predominant function of assimilation, which devolves on the green cells of plants, and which manifests itself under the influence of light in the absorption of carbonic acid and the exhalation of oxygen.

It must not, however, be supposed that the respiration of plants is entirely independent of life. The conditions which bring the oxygen of the air and the combustible matter of the respiring plant into such relations as may allow them to act on one another are still under its control, and we must conclude that in Claude Bernard's experiment the anæsthesia had not been carried so far as to arrest such properties of the living tissues as are needed for this.

The quite recent researches of Schützenberger, who has investigated the process of respiration as it takes place in the cell of the yeast fungus, have shown that vitality is a factor in this process. He has shown that fresh yeast, placed in water, breathes like an aquatic animal, disengaging carbonic acid, and causing

the oxygen contained in the water to disappear. That this phenomenon is a function of the living cell is proved by the fact that, if the yeast be first heated to 60° C. and then placed in the oxygenated water, the quantity of oxygen in the water remains unchanged; in other words, the yeast ceases to breathe.

Schützenberger has further shown that light exerts no influence on the respiration of the yeast cell—that the absorption of oxygen by the cell takes place in the dark exactly as in sunlight. On the other hand, the influence of temperature is well marked. Respiration is almost entirely arrested at temperatures below 10° C., it reaches its maximum at about 40° C., while at 60° C. it again ceases.

All this proves that the respiration of living beings is identical, whether manifested in the plant or in the animal. It is essentially a destructive phenomenon—as much so as the burning of a piece of charcoal in the open air, and, like it, is characterised by the disappearance of oxygen and the formation of carbonic acid.

One of the most valuable results of the recent careful application of the experimental method of research to the life phenomena of plants is thus the complete demolition of the supposed antagonism between respiration in plants and that in animals.

I have thus endeavoured to give you in a few broad outlines a sketch of the nature and properties of one special modification of matter, which will yield to none other in the interest which attaches to its study, and in the importance of the part allocated to it in the economy of nature. Did the occasion permit I might have entered into many details which I have left untouched; but enough has been said to convince you that in protoplasm we find the only form of matter in which life can manifest itself; and that, though the outer conditions of life—heat, air, water, food—may all be present, protoplasm would still be needed, in order that these conditions may be utilised, in order that the energy of lifeless nature may be converted into that of the countless multitudes of animal and vegetable forms which dwell upon the surface of the earth or people the great depths of its seas.

We are thus led to the conception of an essential unity in the two great kingdoms of organic Nature—a structural unity, in the fact that every living being has protoplasm as the essential matter of every living element of its structure; and a physiological unity, in the universal attribute of irritability which has its seat in this same protoplasm, and is the prime mover of every phenomenon of life.

We have seen how little mere form has to do with the essential properties of protoplasm. This may shape itself into cells, and the cells may combine into organs in ever-increasing complexity, and protoplasm force may be thus intensified, and, by the mechanism of organisation, turned to the best possible account; but we must still go back to protoplasm as a naked formless plasma if we would find—freed from all non-essential complications—the agent to which has been assigned the duty of building up structure and of transforming the energy of lifeless matter into that of living.

To suppose, however, that all protoplasm is identical where no difference cognisable by any means at our disposal can be detected would be an error. Of two particles of protoplasm, between which we may defy all the power of the microscope, all the resources of the laboratory, to detect a difference, one can develop only to a jelly-fish, the other only to a man, and one conclusion alone is here possible—that deep within them there must be a fundamental difference which thus determines their inevitable destiny, but of which we know nothing, and can assert nothing beyond the statement that it must depend on their hidden molecular constitution.

In the molecular condition of protoplasm there is probably as much complexity as in the disposition of organs in the most highly differentiated organisms; and between two masses of protoplasm indistinguishable from one another there may be as much molecular difference as there is between the form and arrangement of organs in the most widely separated animals or plants.

Herein lies the many-sidedness of protoplasm; herein lies its significance as the basis of all morphological expression, as the agent of all physiological work, while in all this there must be an adaptiveness to purpose as great as any claimed for the most complicated organism.

From the facts which have been now brought to your notice there is but one legitimate conclusion—that life is a property of protoplasm. In this assertion there is nothing that need startle us. The essential phenomena of living beings are not so widely separated from the phenomena of lifeless matter as to render it impossible to recognise an analogy between them; for even irritability, the one grand character of all living beings, is not more difficult to be conceived of as a property of matter than the physical phenomena of radial energy.

It is quite true that between lifeless and living matter there is a vast difference, a difference greater far than any which can be found between the most diverse manifestations of lifeless matter. Though the refined synthesis of modern chemistry may have succeeded in forming a few principles which until lately had been deemed the proper product of vitality, the fact still remains that no one has ever yet built up one particle of living matter out of lifeless elements—that every living creature, from the simplest dweller on the confines of organisation up to the highest and most complex organism, has its origin in pre-existent living matter—that the protoplasm of to-day is but the continuation of the protoplasm of other ages, handed down to us through periods of indefinable and indeterminable time.

Yet with all this, vast as the differences may be, there is nothing which precludes a comparison of the properties of living matter with those of lifeless.

When, however, we say that life is a property of protoplasm, we assert as much as we are justified in doing. Here we stand upon the boundary between life in its proper conception, as a group of phenomena having irritability as their common bond, and that other and higher group of phenomena which we designate as consciousness or thought, and which, however intimately connected with those of life, are yet essentially distinct from them.

When the heart of a recently-killed frog is separated from its body and touched with the point of a needle, it begins to beat under the excitation of the stimulus, and we believe ourselves justified in referring the contraction of the cardiac fibres to the irritability of their protoplasm as its proper cause. We see in it a remarkable phenomenon, but one nevertheless in which we can see unmistakable analogies with phenomena purely physical. There is no greater difficulty in conceiving of contractility as a property of protoplasm than there is of conceiving of attraction as a property of the magnet.

When a thought passes through the mind, it is associated, as we have now abundant reason for believing, with some change in the protoplasm of the cerebral cells. Are we, therefore, justified in regarding thought as a property of the protoplasm of these cells, in the sense in which we regard muscular contraction as a property of the protoplasm of muscle? or is it really a property residing in something far different, but which may yet need for its manifestation the activity of cerebral protoplasm?

If we could see any analogy between thought and any one of the admitted phenomena of matter, we should be justified in accepting the first of these conclusions as the simplest, and as affording a hypothesis most in accordance with the comprehensiveness of natural laws; but between thought and the physical phenomena of matter there is not only no analogy, but there is no conceivable analogy; and the obvious and continuous path which we have hitherto followed up in our reasonings from the phenomena of lifeless matter through those of living matter here comes suddenly to an end. The chasm between unconscious life and thought is deep and impassable, and no transitional phenomena can be found by which as by a bridge we may span it over; for even from irritability, to which, on a superficial view, consciousness may seem related, it is as absolutely distinct as it is from any of the ordinary phenomena of matter.

It has been argued that because physiological activity must be a property of every living cell, psychical activity must be equally so, and the language of the metaphysician has been carried into biology, and the "cell soul" spoken of as a conception inseparable from that of life.

That psychical phenomena, however, characterised as they essentially are by consciousness, are not necessarily coextensive with those of life, there cannot be a doubt. How far back in the scale of life consciousness may exist we have as yet no means of determining, nor is it necessary for our argument that we should. Certain it is that many things, to all appearance the result of volition, are capable of being explained as absolutely unconscious acts; and when the swimming swarm-spore of an alga avoids collision, and, by a reversal of the stroke of its cilia, backs from an obstacle lying in its course, there is almost certainly in all this nothing but a purely unconscious act. It is but a case in which we find expressed the great law of the adaptation of

living beings to the conditions which surround them. The irritability of the protoplasm of the ciliated spore responding to an external stimulus sets in motion a mechanism derived by inheritance from its ancestors, and whose parts are correlated to a common end—the preservation of the individual.

But even admitting that every living cell were a conscious and thinking being, are we therefore justified in asserting that its consciousness, like its irritability, is a property of the matter of which it is composed? The sole argument on which this view is made to rest is that from analogy. It is argued that because the life phenomena, which are invariably found in the cell, must be regarded as a property of the cell, the phenomena of consciousness by which they are accompanied must be also so regarded. The weak point in the argument is the absence of all analogy between the things compared, and as the conclusion rests solely on the argument from analogy, the two must fall to the ground together.

In a lecture[1] to which I once had the pleasure of listening—a lecture characterised no less by lucid exposition than by the fascinating form in which its facts were presented to the hearers, Prof. Huxley argues that no difference, however great, between the phenomena of living matter and those of the lifeless elements of which this matter is composed should militate against our attributing to protoplasm the phenomena of life as properties essentially inherent in it; since we know that the result of a chemical combination of physical elements may exhibit physical properties totally different from those of the elements combined; the physical phenomena presented by water, for example, having no resemblance to those of its combining elements, oxygen and hydrogen.

I believe that Prof. Huxley intended to apply this argument only to the phenomena of life in the stricter sense of the word. As such it is conclusive. But when it is pushed further, and extended to the phenomena of consciousness, it loses all its force. The analogy, perfectly valid in the former case, here fails. The properties of the chemical compound are like those of its components, still physical properties. They come within the wide category of the universally accepted properties of matter, while those of consciousness belong to a category absolutely distinct—one which presents not a trace of a connection with any of those which physicists have agreed in assigning to matter as its proper characteristics. The argument thus breaks down, for its force depends on analogy alone, and here all analogy vanishes.

That consciousness is never manifested except in the presence of cerebral matter or of something like it, there cannot be a question; but this is a very different thing from its being a property of such matter in the sense in which polarity is a property of the magnet, or irritability of protoplasm. The generation of the rays which lie invisible beyond the violet in the spectrum of the sun cannot be regarded as a property of the medium which by changing their refrangibility can alone render them apparent.

I know that there is a special charm in those broad generalisations which would refer many very different phenomena to a common source. But in this very charm there is undoubtedly a danger, and we must be all the more careful lest it should exert an influence in arresting the progress of truth, just as at an earlier period traditional beliefs exerted an authority from which the mind but slowly and with difficulty succeeded in emancipating itself.

But have we, it may be asked, made in all this one step forward towards an explanation of the phenomena of consciousness or the discovery of its source? Assuredly not. The power of conceiving of a substance different from that of matter is still beyond the limits of human intelligence, and the physical or objective conditions which are the concomitants of thought, are the only ones of which it is possible to know anything, and the only ones whose study is of value.

We are not, however, on that account forced to the conclusion that there is nothing in the universe but matter and force. The simplest physical law is absolutely inconceivable by the highest of the brutes, and no one would be justified in assuming that man had already attained the limit of his powers. Whatever may be that mysterious bond which connects organisation with psychical endowments, the one grand fact—a fact of inestimable importance—stands out clear and freed from all obscurity and doubt, that from the first dawn of intelligence there is with every advance in organisation a corresponding advance in mind. Mind as well as body is thus travelling onwards through higher and still higher phases; the great law of Evolution is shaping the destiny of our race; and though now we may at most but indicate some weak point in the generalisation which would refer consciousness as well as life to a common material source, who can say that in the far off future there may not yet be evolved other and higher faculties from which light may stream in upon the darkness, and reveal to man the great mystery of Thought?

SECTION D

BIOLOGY

Opening Address by Prof. St. George Mivart, F.R.S., Sec.L.S., V.P.Z.S., President of the Section

In responding to the honour which the authorities of the British Association have conferred in nominating me to fill this chair, I have deemed it best not to occupy your very valuable time with any matter of detail at which I may happen to have worked, but rather to offer to you a few remarks on questions which seem to me to have a general biological interest.

Last year my esteemed friend, Prof. Flower, called your attention to the great name of Linnæus. I propose this year to refer to Linnæus's illustrious contemporary, Buffon—not, however, in the character of a rival of Linnæus. Each was a man of genius, each did good work in his own way—work still bringing forth fruit. It must be admitted, however, that they were men of a very different stamp, and if it is necessary to express a relative judgment with respect to them, I should myself feel inclined to say that Buffon's mind had the greater aptitude for sagacious speculation, with an inferior power of acquiring and arranging a knowledge of facts of structure.

Various circumstances have concurred to favour our recollection of the merits of the great Swede, and to obscure those of the French naturalist. The well-earned fame of Linnæus is kept ever fresh in our memories by the necessarily frequent references to him in matters of nomenclature. On the other hand, not only are Buffon's claims on our esteem in no similar way brought before us, but those very speculative opinions of his, which are a merit in our eyes, have gained him disfavour with our immediate predecessors, whose opinions and sentiments we more or less inherit.

No one, however, can dispute Buffon's title to our grateful respect on account of the very powerful effect his writings had in stimulating men's love of nature, an effect which I think is not sufficiently appreciated.

It is fitting that I should call attention to his (once generally recognised) claims in this respect; since my own love of natural history is probably due to the circumstance that his great work was always accessible to me in my childhood, and was one of the earliest books with the pictures of which I was familiar.

Buffon was indeed Linnæus's contemporary, for the same year (1707) saw the births of both. In 1733 he was elected a member of the Academy of Sciences, and six years later was appointed superintendent of the Jardin du Roi,[1] which was the occasion of that work to which he is indebted for his fame, and to perfect which he displayed so much zeal in collecting specimens and in obtaining information respecting the various kinds of animals with which he became acquainted. His "Histoire Naturelle générale et particulière" began to appear in 1749, and in 1767 was published the fifteenth volume, which closed his history of mammals. Herein are contained those numerous anatomical illustrations (due, with their accompanying descriptions, to Daubenton) which have been again and again copied down to the present time. Next came nine volumes on birds, then his history of minerals, and, finally, seven supplementary volumes, the last of which appeared in 1789, the year after his death. His life was thus prolonged ten years beyond that of his illustrious contemporary, Linnæus.

Buffon can claim no merit as a classifier. With the exception of the Apes of the old and new worlds (which respectively fill the fourteenth and fifteenth volumes of his work), the beasts treated of are hardly arranged on any system, beyond that of beginning with the best known and most familiar—a system necessarily applicable to but a few forms.

[1] The Jardin du Roi was first instituted by Louis XIII. in 1628, and definitively established in 1635. It cannot be affirmed that Buffon enriched the incipient museum—the Cabinet du Roi—so much as might have been expected; although the skeletons which served for Daubenton's descriptions were, at least in many instances, preserved. It is to Geoffroy St. Hilaire that the magnificent museum of the Jardin des Plantes, which now exists, is most indebted.

But Buffon deliberately rejected the Linnæan classification—a grave error, certainly, yet one not altogether without excuse. Indeed, some of the objections he brought against that classification have considerable force. Such were his objections to the association of the hippopotamus, the shrew-mouse, and the horse in one order, and of the monkey and the manis in another.[1] What indeed could be more preposterous than the separation of the bat, *Noctilio leporinus*, from the other bats, and its association with the rodents, on the ground of its having (as supposed) only two incisor teeth above and two below?—an anomaly of arrangement of which you were reminded last year. It scarcely seems possible for the pedantry of classification to go farther than this. Yet, perhaps, the association in one group of the walrus, the elephant, the ant-eater, the sloth, and the manatee, was hardly less unphilosophical. Moreover, zoologists should not forget, in blaming Buffon for his want of appreciation of the classification of Linnæus, that one great portion of that classification—the classification of plants—has been superseded by us. Had he lived to witness the publication of Jussieu's "Genera Plantarum,"[2] it might have given him a truer insight into biological classification, and have led him to endeavour to improve on Linnæus' system instead of only criticising it.

But it is Buffon's speculative views which have most interest for us. Those views exercised a very wide-spread influence in their day, though the time was not ripe for them. Indeed, it is far from improbable that writers whose speculations have been made public at a more propitious season, owe much to their comparatively forgotten predecessor.

Amongst Buffon's various speculations we might glance at his "Théorie de la Terre" (put forth in the very first volume of his work), and at his "Epoques de la Nature," which fills the fifth volume of his supplement. We might consider his speculations concerning the formation of mountain and valley by water, and the evidence that there was present to the ear of his imagination:—

"The sound of streams, which, swift or slow,
Tear down Æolian hills and sow
The dust of continents to be."

That he saw, in thought, the projection of the planets from the sun's mass; the primitive fluidity of the earth, and the secular refrigeration of the sun. Such considerations, however, are foreign to this section. I will therefore select two which are of biological interest.

In the first place I may refer to Buffon's speculations concerning ANIMAL VARIATION. In this matter Isidore Geoffroy St. Hilaire has affirmed that Buffon stands to the doctrine of animal variability in a position analogous to that in which Linnæus stands to the doctrine of the fixity of species.

Buffon, in his chapter on the animals of the Old and New World, remarks,[3] "It is not impossible that the whole[4] of the new world's animals are derived from the same source as those of the old, whence they have descended." . . . . "Nature is in a state of perpetual flux." In this chapter on the degeneration of animals[5] he sums up saying, "After comparing all the animals, and arranging them each in their own group, we shall find that the two hundred kinds described here may be reduced to a small number of original forms, whence it may be all the rest have issued."

As to the modes and causes of the origin of new forms, he entertained four connected opinions:

(1) He attributed much modifying efficacy to migrations;

(2) Also to the direct action of external conditions;

(3) He believed largely in the origin of new forms by degradation; and

(4) He regarded each animal as the manifestation of an individuating force, living, as it were, at the root of the changes manifested by it.

The view that MIGRATION (with isolation) is a necessary antecedent to the origin of new species is one which has been advocated by a modern naturalist, Moritz Wagner;[6] who does not hesitate to affirm[7] that the formation of a nearly new species "will only succeed when a few individuals, having crossed the barriers of their station, are able to separate themselves for a long time from the old stock."

In support of his view the author brings forward a multitude of interesting facts, one of the most significant of which appears to me to be the following. It concerns Beetles of Tropical America of the genus *Tetracha*. In Venezuela, and in the western part of Central America, he tells us rivers flow partly through savannahs, where they have undermined the light tufaceous soil, forming deep beds with high precipitous banks. According to Prof. Wagner, individual beetles from the highlands have thus been isolated, and in no longer time than has been required by the rivers to undermine the loose soil of the savannah, have given rise to a distinct species markedly different in form and colour. It is to similar causes—migration and complete isolation—that he traces the formation of distinct races of men: a formation he deems no longer possible, while the wide diffusion of mankind renders more and more difficult the evolution of new species of animals of any kind.

Instances which appear to support this view will readily suggest themselves to the naturalist—instances, that is, of forms which are both peculiar in structure and remote and isolated as to their habitat.[1] Thus for example, even in the group which structurally most resembles us, we have the Orang confined to very limited tracts in Borneo and Sumatra, and the Gorilla to a small portion of Western Africa. The Proboscis Monkey is found nowhere but in Borneo, while the singular ape named "Roxellana," (from its wonderfully "tip-tilted" nose) is confined to the lofty and isolated mountains of Monpin in Thibet. The very peculiar black ape (*Cynopithecus*) is limited to Celebes and Batchian, while the Baboon, which has the baboon character of muzzle most developed, was found at the extreme south of the African continent.

Again, if we take the group of Lemur-like animals (*Lemuroidea*) as having had their home and starting-point in or near their present head-quarters—Madagascar—then some of the most aberrant forms are those which must have migrated farthest. The character which is perhaps the most peculiar of any which the group presents, is the elongation of two of the ankle-bones, as we find it in the Madagascar genus *Cheirogaleus*. But this character is more exaggerated in migrants to Africa—the Galagos—and most so of all in the more isolated emigrant, the Tarsier, now found in Celebes and Borneo.

The sub-family of slow-lemurs (*Nycticebinæ*) would, on this view, seemed to have migrated in opposite directions, as we find the slender slow-lemur (*Loris*) in Madras, Malabar, and Ceylon; the typical slow-lemur (*Nycticebus*) in South China, Borneo, and Java; the Potto (*Perodicticus*) in Sierra Leone, and the Angwantibo (*Arctocebus*) in Old Calabar. Of these, it is the African forms which have the index-finger most atrophied—a tendency to its atrophy existing in the whole sub-family.

It would, of course, be very easy to multiply instances of the kind; but it would be also easy to cite a number of cases which appear to conflict with the view in question. Thus familiar to us as it is, few animals are more peculiar in structure than the common mole, which gives no present evidence of isolated origin; and the most aberrant of all bats, the Vampire (*Desmodus*), is rather widely distributed in South America. Again, with regard to the Lemur group, the most absolutely exceptional is the Aye-Aye (*Cheiromys*), which, on the hypothesis supposed, has remained persistently at the head-quarters of the group, *i.e.* in Madagascar.

Even, however, if no exception existed to the co-existence now of singularity of form and isolation and remoteness of situation, we could not safely draw any decided conclusion from such facts, because fossil remains show us that forms which have now a very limited distribution, were either widely spread in earlier times, or existed in regions very remote from those they now inhabit. Thus, in Eocene times there existed in Europe true opossums (now confined to America), Tapirs, and a form like the African Potto before mentioned. In Miocene times we had in Europe long-armed apes (creatures now found only in Eastern Asia), with the now exclusively African Secretary Bird and Cape Ant Eater (*Orycteropus*). In the same period the Orang—or a nearly allied form—seems to have ranged over

[2] This appeared in 1789.

[3] *Op. cit.* vol. ix. p. 127.

[4] He thought that the American Jaguars, Ocelots, &c., and even the Peccary, were positive degradations of old world forms. He thought that the Llama, the American Apes, Agoutis, and Ant-eaters might be examples of such forms; but the Opossum, Sloths, and Tapirs he took to be original species. (See vol. xiv. pp. 272, 273.)

[7] *Op. cit.* p. 29.

[1] Isolation, it ought to be remembered, may take place as the result not only of changes in inorganic nature (such as the formation of islands, and the excavation of river beds), but also by the presence of enemies in intermediate tracts, by the circumstance that the food of the species is found only in certain restricted localities, and by whatever other causes determine the extinction of a species in a given place.

India. What are more emphatically old world forms than the camel, horse, and elephant, with the typical porcupine? Yet all these existed in America in Pliocene times. Did we know the Tapir in only one of the two widely-separated stations in which it dwells to-day, we might well deem its evolntion to be due to migration and isolation. But we know from palæontology that it existed in Europe from the Eocene to the Pliocene period.

Such facts as these do not, of course, disprove the doctrine that migration and isolation are necessary antecedent conditions to specific genesis, but they show how much caution must be used in drawing the conclusion that they are necessary, from the distribution of animals much less likely to be found fossil than mammals are.

But an argument in favour of the views of Buffon and of Wagner may be obtained from our own species, which exhibits some singular coincidences between peculiarity of form and isolation. Among such instances may be mentioned the Tasmanians, the Andaman Islanders, and the Aïnos or Aborigines of Japan. One of the most striking examples is that of the Eskimo—a people representing many peculiarities, some of which exaggerate the characters of the highest races of mankind. Thus, the pelvis differs from the European pelvis in an opposite direction to that by which the negro pelvis differs from the European, and the same is the case with the proportions of the limbs, while the skulls of the Eskimo have the largest and narrowest nasal aperture of all races, being in this respect the very opposite to the Australians. The Eskimo have migrated eastwards, not reaching the south of Greenland till the fourteenth century, and the race characters are most marked in the most easterly tribes. These facts were brought forward by Prof. Flower in his Hunterian lectures for the present year,[1] when he said that the characters of this peculiar race "must be attributed to those gradual modifications produced by causes at present little understood, by which most of the striking variations met with in the human species have been brought about—modifications more strongly expressed the more completely isolated the race has become, and the farther removed from its original centre of distribution." I think, then, that though we have not data for conclusively answering the question as to how far migration (together with isolation) may be necessary for specific genesis, it is certain that it is of very great efficacy and importance, and that credit is justly due to Buffon for his early appreciation of its importance.

The next question to which I would advert is that concerning THE DIRECT ACTION UPON ORGANISMS, OF THE EXTERNAL CONDITIONS WHICH SURROUND THEM.

Buffon's belief was[2] that changes of specific form were brought about by change of temperature and climatic change generally, as well as by change of food.

The curious effects of stimulating food on colour—as of cayenne pepper with canaries, and hemp-seed with parrots—is notorious.

The direct action of the environment on organisms has, I think, been of late somewhat undervalued. Amongst evidences in favour of its importance, I would refer to some of Mr. Alfred Wallace's observations.[3] He tells us that in the small island of Amboina, the butterflies (twelve species of nine different genera) are larger than those of any of the more considerable islands about it, and that this is an effect plainly due to some local influence. In Celebes, a whole series of butterflies are not only of a larger size, but have the same peculiar form of wing. The Duke of York's Island seems, he tell us, to have a tendency to make birds and insects white or at least pale, and the Philippines, to develop metallic colours, while the Moluccas and New Guinea seem to favour blackness and redness in parrots and pigeons. Species of butterflies which in India are provided with a tail to the wing, begin to lose that appendage in the islands, and retain no trace of it on the borders of the Pacific. The Æneas group of Papilios never have tails in the equatorial region of the Amazon Valley, but gradually acquire tails, in many cases, as they range towards the northern and southern tropics. Mr. Gould says that birds are more highly coloured under a clear atmosphere than in islands or on coasts—a condition which also seems to affect insects, while it is notorious that many shore plants have fleshy leaves. I need but refer to the English oysters mentioned by Costa, which, when transported to the Mediterranean, grew rapidly like the true Mediterranean oyster, and to the twenty different kinds of American trees, said by Meehan to differ in the *same manner* from their nearest European allies, as well as to the dogs, cats, and rabbits which have been proved to undergo modifications directly induced by climatic change.

It appears, then, that much may be said in favour of that direct effect of surrounding circumstances on organisms in which Buffon believed.

Lastly, I would refer to Buffon's belief that new species have arisen by DEGRADATION. This again is an opinion which, after a period of disfavour, or at least of neglect, has been of late revived, and has acquired considerable influence. I may here refer to Anton Dohrn, who has recently advocated the very widely-spread and effective action of degradation as a cause of specific change. It will, I think, be generally admitted that such exceptional Copepod crustaceans as *Tracheliastes* and *Lernæocera* are due to degradation, and the probability seems to me very strong that the Rhizocephala, at least many cirripeds, and the certoid worms, are also degraded organisms. Very interesting would it be to know whether existing Ascidians are also examples of degradation, as not a few zoologists now suppose; but most interesting of all is that parasite of cuttle fishes, *Dicyema*, the structure of which has been recently investigated by Prof. Eduard van Beneden, and made the type of a new primary division of animals. Should this small worm-like organism hereafter turn out to be a degraded form, it will show what an extreme degree of retrograde metamorphosis may occasionally be brought about. I think, then, that we have considerable ground for suspecting that degradation has acted much and widely in the field of Biology, and if so, Buffon is fairly entitled to a certain amount of esteem on account of the views he entertained with regard to it in so early a day and in so undeveloped a condition of zoological science. For it must not be forgotten that migration, the influence of external conditions, and degradation, are connected points: parts of one view. Degradation is most conspicuous under violent changes of condition (such as parasitism), while migration only acts by bringing organisms under new conditions.

These reflections lead me to urge upon such of my hearers as may have any unusual facilities for experimental investigation, a course of inquiry which seems to be very desirable.

What is needed in order to solve as far as possible the question of specific genesis, is a knowledge of the laws of variation, which must, I think, be deemed the true cause and origin of species.

We may, I think, accept as true two propositions:—

1. Animals may change in various ways, and amongst them, by degradation.

2. Changes in the environment with isolation, induce and favour changes in form.

I would urge, then, that inquiries should be pursued in two directions simultaneously.

A. There might be undertaken one set of inquiries to investigate the effects on different species of the same variations of environment.

B. Other inquiries might be undertaken with a view to ascertaining the effects of different changes of environment on one and the same species. By series of experiments contrived with these ends in view, and carried on with various selected animals and plants which reproduce with rapidity, we may possibly be able to determine what to attribute to external influences (shown by such influence having the same effects on all), and what to the peculiar nature and innate powers and tendencies of different organisms—shown by the diverging reactions of the latter under the same changes in their environment.

I next desire to direct your attention to another matter treated of by Buffon—I mean THE RESEMBLANCES AND DIFFERENCES WHICH EXIST BETWEEN THE MIND OF MAN AND THE HIGHER PSYCHICAL FACULTIES OF ANIMALS.

This question is eminently a question of our own day, and one which I feel cannot but excite interest in this section.

But its accurate investigation is attended with special difficulties, and amongst them are two temptations, which are apt to beset the inquirer;

1. The first of these arises from the wide-spread love for the marvellous of whatsoever kind, and the tendency to inverted anthropomorphism.

[1] The lecturer also said: "The large size of the brain of all the hyperborean races, Lapps as well as Eskimo, seems not necessarily to be connected with intellectual development, but may have some other explanation not at present apparent." I would suggest that in this case—as in the large brains of Cetaceans—it may be due to the need in their climate of generating much heat to sustain the necessary temperature of the body.

[2] *Op. cit.*, vol. xiv. p. 317.

[3] See "Tropical Nature," pp. 254–259.

2. The other is the temptation to strain or ignore facts to serve a favourite theory.

As to the former of these dangers, I may perhaps be permitted to quote some remarks made by Mr. Chambers, approvingly cited by Prof. Bain: "There are two subjects where the love of the marvellous has especially retarded the progress of correct knowledge—the manners of foreign countries, and the instincts of the brute creation. . . . . It is extremely difficult to obtain true observations" as to the latter "from the disposition to make them subjects of marvel and astonishment." . . . . "It is nearly as impossible to acquire a knowledge of animals from anecdotes as it would be to obtain a knowledge of human nature from the narratives of parental fondness and friendly partiality." This I believe to be most true, and that here the danger of mistaking inference for observation is exceptionally great. The inquirer ought not to accept as facts marvellous tales without criticism and a careful endeavour to ascertain whether the alleged facts are facts and not unconscious fictions.

As to the second danger, the lamented George Henry Lewes, whom no one can suspect of any hostility to evolution in its most extreme form, remarks (in his posthumous work[1] just published) that the researches of various eminent writers on animal psychology have been "biassed by a secret desire to establish the *identity* of animal and human nature," and certainly no one can deny that those who do assert that identity, are necessarily exposed to the temptation referred to. Of course persons who desire to disprove this identity are exposed to the opposite temptation; but it cannot be maintained that there is evidence of Buffon having been influenced by any such desire.

The obvious difference between the highest powers of man and animals has led the common sense of mankind to consider them to be of radically distinct kinds, and the question which naturalists now profess to investigate is whether this is so or no.

But we may doubt, whether many who enter upon this inquiry do not enter upon it with their minds already made up that no such radical difference can by any possibility exist. To admit it, they think, would be tantamount to admitting some non-natural origin of man, to accepting, as a fact, something not harmonising with our views as to nature generally, leading to we know not what results—possibly even to lending some support to Christianity. To admit it, would be to deny the principle of continuity. There cannot, therefore, be any essential difference between man and brute, and their mental powers must be the same in kind. This, I think, is no unfair representation of the state of mind in which this question is very likely to be entered upon at the present time. Surely, however, if we profess to investigate a question, we ought in honesty to believe that there *is* a question to investigate, or else leave the matter to others; and if evidence should seem to show that "intellect" *cannot* be analysed into sense, but is an ultimate, it ought to be accepted, at the least provisionally, as such, even at the cost of having to regard its origin as at present inexplicable. Can we explain the origin of "motion?" But what rational man thinks of denying it on that account? Let us not reject anything, then, which may be evident, on account of certain supposed speculative consequences.

But that no such consequences as those referred to need follow from the admission of the radical distinctness of human reason, seems evident from the views of Aristotle. He certainly was free from theological prejudices or predispositions, and yet to his clear intellect the difference between the merely sentient and the rational natures was an evident difference, and the facts which are open to our observation are the same as those which presented themselves to his.

To enter on this inquiry with any fair prospect of success, it is not only necessary to guard against such temptations as these, but it is also necessary to be provided with a certain amount of knowledge of a special kind; namely, with a clear knowledge of what our own intellectual powers are. I conceive that, great as is the danger of exaggeration and false inference as to the faculties of animals, the danger of misapprehending and underrating our own powers is far greater.

Buffon held very decided views as to the distinctness of the mind of man from the so-called minds of animals. But an ingenious and gifted writer,[2] who has recently done good service in supporting Buffon's claims to greater consideration than he commonly receives, has, nevertheless, done him what I believe to be strange injustice in attributing to his great work an ironical character, and this in spite of Buffon's protest[1] against irony in such a work as his. I cannot venture to take up your time with controversy on this subject; but apart from Buffon's protest against "équivoque," it is incredible to me that he should have carried on a sustained irony through so voluminous a work—thus making its whole teaching absolutely mendacious. One remark of Buffon's, which has been strangely misinterpreted by this writer, I shall have occasion to notice directly; but I think it may suffice to clear Buffon's character from the aspersion of his admiring assailant, to point out that in the table of contents in the final volume of his "History of Mammals"[2] (which table gives the pith and gist of his several treatises), he distinctly affirms the distinctions maintained in the body of his work.

[1] "Problems of Life and Mind." Third Series, 1879, p. 122.

[2] Mr. Samuel Butler. See his "Evolution, Old and New." (Hardwicke and Bogue, 1879.)

The following were Buffon's views. In his "Discourse on the Nature of Animals,"[3] he says, "Far from denying feelings to animals, I concede to them everything except thought and reflection" . . . . "they have sensations, but no faculty of comparing them one with another, that is to say, they have not the power which produces ideas." He is full of scorn[4] for that gratuitous admiration for the moral and intellectual faculties of bees, which Sir John Lubbock's excellent observations and experiments have shown to be indeed gratuitous. Speaking of the ape, most man-like (and *so* man-like) as to brain, he says:[5] "Il ne pense pas: y a-t-il une preuve plus évidente que la matière seule, quoique parfaitement organisée, ne peut produire ni la pensée, ni la parole qui en est le signe, à moins qu'elle ne soit animée par un principe supérieur?"[6] Buffon has been accused of vacillation with respect to his doctrine concerning animal variation, but no one has accused him of vacillation with respect to his views concerning reason and instinct.

I come now to the passage which I said has been so strangely misunderstood. It is that in which he expresses his conviction that "animals have no knowledge of the past, no idea of time, and consequently no memory." But to quote this passage without explanation is gravely to misrepresent the illustrious French naturalist. Buffon was far from ignoring, indeed he distinctly enumerates the various obtrusive phenomena which often lead the vulgar to attribute, without qualification, both knowledge and memory to brutes. But, in fact, he distinguishes between[7] memory and memory. His words are: "Si l'on a donné quelque attention à ce que je viens de dire, on aura déjà senti que je distingue deux espèces de mémoire infiniment différentes l'une de l'autre par leur cause, et qui peuvent cependant se ressembler en quelque sorte par leurs effets; la première est la trace de nos idées, et la seconde, que j'appellerais volontiers réminiscence[8] plutôt que mémoire, n'est que le renouvellement de nos sensations," and he declares[9] true memory to consist in the recurrence of ideas as distinguished from revived sensuous imaginations.

This distinction is one which it is easy to perceive. That we have automatic memory, such as animals have, is obvious; but the presence of intellectual memory (or memory proper) may be made evident by the act of searching our minds (so to speak) for something which we know we have fully remembered before, and thus intellectually remember to have known, though we cannot now bring it before our imagination.

As with memory, so with other of our mental powers, we may, I think, distinguish between a higher and a lower faculty of each; between our higher, self-conscious, reflective mental acts—the acts of our intellectual faculty—and those of our merely sensitive power. This distinction (to which I have elsewhere[10] called attention) I believe to be one of the most fundamental of all the distinctions of biology, and to be one the apprehension of which is a necessary preliminary to a successful investigation of animal psychology. It is, of course, impossible for us thoroughly to comprehend the minds of dogs or birds, because we cannot enter into the actual experience of such animals, but by understanding the distinction between our own higher and

[1] *Op. cit.* tome i. p. 25. [2] *Op. cit.* tome xv. [3] *Op. cit.* tome iv. p. 41.

[4] *Op. cit.* tome iv. p. 91. [5] *Op. cit.* tome xiv. p. 61.

[6] Mr. Butler cites objections brought forward in a certain passage (from pp. 30 and 31, vol. xiv.), as if they were Buffon's own. But they are the objections of an imagined opponent whose views Buffon himself combats. It is worthy of note that Buffon long anticipated our contemporaries with respect to man's place in nature in so far as concerns his mere anatomy. For he did not hesitate to affirm that the Orang differs less from us structurally than it differs from some other apes.

[7] *Op. cit.* tome iv. p. 60.

[8] Here he follows, without citing, the old distinction of Aristotle between memory and reminiscence.

[9] *Op. cit.* tome iv. p. 56.

[10] "Lessons from Nature" (Murray, 1876), p. 196.

lower faculties,[1] we may, I think, more or less approximate to such a comprehension.

It may, I believe, be affirmed that no animal but man has yet been shown to exhibit true concerted action, or to express by external signs distinct intellectual conceptions—processes of which all men are normally capable. But just as some plants simulate the sense perception, voluntary motions and instincts of animals, without there being a real identity between the activities thus superficially similar, so there may well be in animals actions simulating the intellectual apprehensions, ratiocinations, and volitions of man without there being any necessary identity between the activities so superficially alike. More than this, it is certain, *à priori*, that there must be such resemblance, since our organisation is similar to that of animals, and since sensations are at least indispensable antecedents to the exercise of our intellectual activity.

I have no wish to ignore the marvellous powers of animals or the resemblance of their actions to those of man. No one can reasonably deny that many of them have feelings, emotions, and sense-perceptions similar to our own; that they exercise voluntary motion and perform actions grouped in complex ways for definite ends; that they to a certain extent learn by experience, and can combine perceptions and reminiscences so as to draw practical inferences, directly apprehending objects standing in different relations one to another, so that, in a sense, they may be said to apprehend relations. They will show hesitation, ending apparently, after a conflict of desires, with what looks like choice or volition, and such animals as the dog will not only exhibit the most marvellous fidelity and affection, but will also manifest evident signs of shame, which may seem the outcome and indication of incipient moral perceptions. It is no great wonder, then, that so many persons, little given to patient and careful introspection, should fail to perceive any radical distinctions between a nature thus gifted and the intellectual nature of man.

But, unless I am greatly mistaken, the question can never be answered by our observations of animals, unless we bear in mind the distinctions between our own higher and lower faculties.

Now I cannot here even attempt to put before you what I believe to be the true view of our own intellectual processes. Still I may, perhaps, be permitted to make one or two passing observations.

Everybody knows his own vivid feelings (or sensations), and those faint revivals of feelings, simple or complex, distinct or confused, which are imaginations and emotions; but the same cannot be said as to thought. Careful introspection will, however, I think, convince any one that a "thought" is a thing widely different from an "imagination"—or revival of a cluster of faint feelings. The simplest element of thought seems to me to be a "judgment," with an intuition of reality concerning some "fact," regarded as a fact real or ideal. Moreover, this judgment is not itself a modified imagination, because the imaginations which may give occasion to it persist unmodified in the mind side by side with the judgment they have called up. Let us take, as examples, the judgments "that thing is good to eat," and "nothing can be and not be at the same time and in the same sense." As to the former, we vaguely imagine "things good to eat," but they exist *beside* the judgment, not *in* it. They can be recalled, compared, and seen to co-exist. So with the other judgment, the mind is occupied with certain abstract ideas, though the imagination has certain vague "images" answering respectively to "a thing being" and "a thing not being," and to "at the same time" and "in the same sense;" but the images do not *constitute* the judgment itself any more than human "swimming" is made up of "limbs and fluid," though without such necessary elements no such swimming could take place.

This distinction is also shown by the fact that one and the same idea may be suggested to, and maintained in, the mind by the help of the most incongruous images, and very different ideas by the very same image. This we may see to be the case with such ideas as "number," "purpose," "motion," "identity," &c.

But the distinctness of "thought" from "imagination" may perhaps be made clearer by the drawing out fully what we really do when we make some simple judgment, as, *e.g.*, that "a negro is black." Here, in the first place, we directly and explicitly affirm that there is a conformity between the external thing, "a negro," and the external quality, "blackness"—the negro possessing that quality. We affirm secondarily and implicitly a conformity between the two external entities and the two corresponding internal concepts. And thirdly, and lastly, we also implicitly affirm the existence of a conformity between the subjective judgment and the objective existence.

All that it seems to me evident that sentience can do is to associate feelings and images of sensible phenomena, variously related, in complex aggregations, but not to apprehend sensations as "facts" at all, still less as internal facts, which are the signs of external facts. It may be conceived as marking successions, likenesses and unlikenesses of phenomena, but not as recognising such phenomena as *true*. Animals, as I have fully admitted, apprehend things in different relations, but no one that I know of has brought any evidence that they apprehend them *as* related, or their relations *as* relations. A dog may feel shame, or possibly (though I do not think probably) a migrating bird may feel agony at the imagination of an abandoned brood; but these feelings have nothing in common with an ethical judgment, such as that of an Australian, who, having held out his leg for the punishment of spearing, judges that he is wounded more than his common law warrants.

Animals, it is notorious, act in ways in which they would not act had they reason; while, as far as I have observed or read, all they do is explicable by the association of sensations, imaginations, and emotions, such as take place in our own lower faculties. We cannot, of course, prove a negative, but we have no right to assume the existence of that for which there is no evidence, without which all the facts can be explained, and which, if it did exist, would make a multitude of observed facts impossible. Apes (like dogs and cats) warm themselves with pleasure at deserted fires, yet, though they see wood burning and other wood lying by, though they have arms and hands as we have, and the same sentient faculties, they have never, so far as I know, been recorded to have added fuel to maintain their comfort. Swallows will continue to build on a house which they see has begun to be pulled down, and no animal can be shown to have made use of antecedent experience to *intentionally* improve upon the past.

If, on the other hand, animals were capable of deliberately acting in concert, the effects would soon make themselves known to us so forcibly as to prevent the possibility of mistake.

Mr. Lewes has not hesitated to affirm[1] that "between animal and human intelligence there is a gap which can only be bridged over by an addition from without," and he also says:[2] "The animal world is a continuum of smells, sights, touches, tastes, pains, and pleasures: it has no objects, no laws, no distinguishable abstractions, such as self and not self. . . . If we see a bud, after we have learned that it is a bud, there is always a glance forward at the flower and backward at the seed . . . . but what animal sees a bud at all except as a visible sign of some other sensation?" As a friend of mine, Prof. Clarke,[3] has put it: "In ourselves sensations presently set the intellect to work; but to suppose that they do so in the dog is to beg the question that the dog has an intellect. A cat to bestir itself to obtain its scraps after dinner, need not entertain any *belief* that the clattering of the plates when they are washed is usually accompanied by the presence of food for it, and that to secure its share it must make certain movements; for quite independently of such belief, and by virtue of mere association, the simple objective conjunction of the previous sounds, movements, and consequent sensations of taste, would suffice to set up the same movements on the present occasion." Let certain sensations and movements become associated, and then the former need not be noted: they only need to exist for the association to produce its effects, and simulate apprehension, deliberation, inference, and volition. "When the circumstances of any present case differ from those of any past experience, but imperfectly resemble those of many past experiences, parts of these, and consequent actions, are irregularly suggested by the laws of resemblance, until some action is hit on which relieves pain or gives pleasure. For instance . . . . let a dog be lost by his mistress in a field in which he has never been before. The presence of the group of

[1] Certain writers (as, for example, Prof. Ewald Hering, of Prague) have used the word "memory" to denote what should properly be called "organic habit," *i.e.*, the power and tendency which living beings have to perpetuate in the future, effects wrought on them in the past. But to call such action, as that by which a tree as it grows, preserves the traces of scars inflicted on it years before, "memory," is a gross abuse of language—a use of the word as unreasonable as would be the employment of the word "sculptor" to denote a quarryman, or "sculpture" to indicate the fractures made in rocks by the action of water and frost.

[1] "Problems of Life and Mind," vol. i. p. 156.

[2] *L.c.*, p. 140.

[3] "Questions on Psychology," p. 9.

sensations which we know to indicate his mistress is associated with pleasure, and its absence with pain. By past experience an association has been formed between this feeling of pain and such movements of the head as tend to recover some part of that group, its recovery being again associated with movements which, *de facto*, diminish the distance between the dog and his mistress. The dog, therefore, pricks up his ears, raises his head and looks round. His mistress is nowhere to be seen; but at the corner of the field there is visible a gate at the end of a lane which resembles a lane in which she has been used to walk. A phantasm (or image) of that other lane, and of his mistress walking there, presents itself to the imagination of the dog; he runs to the present lane, but on getting into it she is not there. From the lane, however, he can see a tree at the other side of which she was wont to sit; the same process is repeated, but she is not to be found. Having arrived at the tree he thence finds his way home." By the action of such feelings, imaginations, and associations—which we know to be *veræ causæ*—I believe all the apparently intelligent actions of animals may be explained without the need of calling in the help of a power, the existence of which is inconsistent with the mass, as a whole, of the phenomena they exhibit.

But if there *is* a radically distinct intellectual power or force in man, is such a distinction of kind so isolated a fact as many suppose? May there not exist between the forces which living beings exhibit other differences of kind?

Each living being consists of an aggregation of parts and functional activities which are evidently knit together into a unity. Each is somehow the seat or theatre of some unifying power or condition which synthesises their varied activities, and is a PRINCIPLE OF INDIVIDUATION. This seems certainly to have been the opinion of Buffon, and it is to this opinion that I referred in speaking of the fourth cause to which he attributed the changes in organic forms. And to me it seems that we must admit the existence of such a living principle. We may analyse the activities of any animal or plant, and by consideration of them separately find resemblances between them and mere physical forces. But the *synthesis* of such forces as we find in a living creature is certainly nowhere to be met with in the inorganic world.

To deny this would be to deny the plainest evidence of our senses. To assert that each living body is made up of minute independent organisms, each with its own "principle of individuation," and without subordination or co-ordination, is but to multiply difficulties, while such a doctrine conflicts with the evidence of our own perceptions, which lead each of us to regard himself as one whole—a true unity in multiplicity.

The existence in each creature of a peculiar, co-ordinating, polar force, seems to be specially pointed to by the phenomena of serial and bilateral symmetry, by the symmetrical character of certain diseases, by the phenomena of monstrous growths and by the symmetrical beauty of such organisms as the Radiolarian Rhizopods.

It also seems to me to be made evident, by the various activities of each animal, which are, as a fact, grouped in one in mutual interaction—an organism having been described by Kant as a creature, the various parts of which are reciprocally ends and means.

I think now I hear the exclamation—This is "Vitalism!" while some of my hearers may deem these matters too speculative for our Section.

But consciously or unconsciously, general conceptions of the kind exist in the minds of all biologists, and influence them in various ways, and their consideration therefore can hardly be out of place here; while as to "Vitalism," I am convinced I shall not be wasting your time in endeavouring to remove a widespread misconception.

The "Vitalism" which is so reasonably objected to, is that which supposes the existence in each living creature of some separate entity inhabiting the body—an extra-organic force within the living creature, and acting by and through it, but numerically distinct from it. But the view which I venture to put before you as that which is to my judgment a reasonable one, is that of a peculiar form of force which is *intra-organic*, so that it and the visible living body are one thing, as the impress on stamped wax and the wax itself are one, though we can ideally distinguish between the two. It is, in fact, a mode of regarding living creatures with prime reference to their activities rather than to their material composition, and every creature can of course be regarded either statically or dynamically. It is to regard any given animal or plant, not as a piece of complex matter played upon by physical forces, which are transformed by what they traverse, but rather as a peculiar immanent principle[1] or form of force (whensoever and howsoever arising), which for a time manifests itself by the activities of a certain mass of complex material, with which it is so entirely one that it may be said to constitute and *be* such animal or plant much rather than the lump of matter which we can see and handle can be said to constitute such animal or plant. On this view a so-called "dead bird" is no bird at all, save by abuse of language, nor is a "corpse" really a "dead man"—such terms being as self-contradictory as would be the expression "a dead living creature."

Thus the real essence, the substantial constituent of every living thing is something which escapes our senses, though its existence and nature reveal themselves to the intellect.

For of course our senses can detect nothing in an animal or plant beyond the qualities of its material component parts. But neither is the function of an organ to be detected save in and by the actions of such organ, and yet we do not deny it its function or consider that function to be a mere blending and mixture of the properties of the tissues which compose it. Similarly it would seem to be unreasonable to deny the existence of a living principle of individuation because we can neither see nor feel it, but only infer it. This power or polar force, which is imminent in each living body, or rather which is that body living, is of course unimaginable by us, since we cannot by imagination transcend experience, and since we have no experience of this force, save as a body living and acting in definite ways.

It may be objected that its existence cannot be verified. But what *is* verification? We often hear of "verification by sensation," and yet even in such verification the ultimate appeal is not really to the senses, but to the intellect, which may doubt and which criticises and judges the actions and suggestions of the senses and imagination. Though no knowledge is possible for us which is not genetically traceable to sensation, yet the ground of all our developed knowledge is not sensational, but intellectual, and its final justification depends, and *must* depend, not on "feelings," but on "thoughts." I must apologise to such an audience as that I have the honour of addressing for expressing truths, which, to some of my hearers, may appear obvious. I would gladly suppress them as superfluous did not my own experience convince me that they are not superfluous. To proceed: "Certainty" does not exist at all in *feelings* any more than doubt. Both belong to thought only. "Feelings" are but the materials of certainty, and though we can be perfectly certain about our feelings, that certainty belongs to thought and to thought only. "Thought," therefore, is our absolute criterion. It is by self-conscious thought only that we know we have any feelings at all. Without thought, indeed, we might feel, but we could not know that we felt or know ourselves as feeling. If, then, we have *rational* grounds for the acceptance of such a purely intellectual conception as that of an immanent principle as the essence of each living creature, the poverty of our powers of imagination should be no bar to its acceptance. We are continually employing terms and conceptions—such, *e.g.*, as "being," "substance," "cause," &c.—which are intelligible to the intellect (since they can be discussed), though they transcend the powers of the imagination to picture.

It seems to me that the spirit which would deny such realities is the same spirit which would deny our real knowledge of an external world at all, and represent any material object as "state of consciousness," and at the very same time represent "a state of consciousness" as the accompaniment of a peculiar state of a material object—the body.[2] This mode of representation may

[1] The word "principle" has been used to denote that activity which, together with material substance, constitutes a living creature, because that word calls up a less sensuous, and therefore less misleading, phantasm than any other. The old term ψυχή, or soul, has in modern times come to be associated with the idea of a substance numerically distinct from the living body, and capable of surviving the destruction of the latter. But as structure and function ever vary together (as do the convexities and concavities of a curved line), so "the principle of individuation" or soul of an animal or plant and its material organisation must necessarily arise, vary, and be destroyed simultaneously, unless some special character, as in the case of man, may lead us to consider it exceptional in nature. Even in man, however, there seems no adequate reason for believing in the existence of any principle of individuation, save that which exerts its energy in all his functions, the humblest as well as the most exalted.

[2] Those who deny that we have a real power of perceiving objects, refute themselves when they speak of "purely physical changes," or of anything "physical" of which feelings are but the "accompaniment" or "subjects." For according to them "matter" is but a term for certain "states of consciousness," while they represent each state of consciousness as a function of matter. According to this, let *a* represent a "state of consciousness, and

be shortly, but not unjustly, described as a process of intellectual "thimble-rigging," by which the unwary spectator is apt to be cheated out of his most valuable mental possession—his rational certainty.

The same spirit asserts that our psychical powers never themselves enter into the circuit of physical causation, and yet few things would seem more certain to a plain man than that (supposing him to have received a message saying his house is on fire) it is his *knowledge* of what has been communicated which sets him in motion. To deny this is to deny the evident teaching of our consciousness. It is to deny what is necessarily the more certain in favour of what is less so. If I do not know this I know *nothing*, and discussion is useless. As a distinguished writer has said: "That we are conscious, and that our actions are determined by sensations, emotions, and ideas, are facts which may or may not be explained by reference to material conditions, but which no material explanation can render more certain." The advocate of "natural selection" may also be asked, How did knowledge ever come to be, if it is in no way useful, if it is utterly without action, and is but a superfluous accompaniment of physical changes which would go on as well without it?

As we may be confident that thought not only is but also acts, as well as that there are things which are not psychical, but which are physical; so I would urge that the conception of living things, which I venture to put before you, is one which may be rationally entertained.

Assuming for the moment and for argument's sake that it may be accepted, what light does our knowledge of ourselves throw upon the intimate life-processes of lower organisms? We know that with us a multitude of actions, which are at first performed with consciousness, come to be performed unconsciously; we know that we experience sensations[1] without perceiving them; we know also that countless organic activities take place in us under the influence and control of the nervous system, which either never rise into consciousness at all, or only do so under abnormal conditions. Yet we cannot but think that those activities are of the same generic nature, whether we feel, perceive, or attend to them or not. The principle of individuation in ourselves, then, evidently acts with intelligence in some actions, with sentience in many actions, but constantly in an unperceived and unfelt manner. Yet we have seen it undeniably intervene in the chain of physical causation.

An animal is an organism all the actions of which are necessarily determined by the adjustments of its various organs, and by its environment. But even its sensations cannot be regarded as mere accompaniments of its activities, but as guides and directing agencies intervening in the circle of its actions, and as facts, in the chain of physical causation. The sight of a stick may change the course of actions which a dog would otherwise have pursued—that is, the feeling of the moment, together with the faint recurrence of various past feelings and emotions therewith associated which the sight of the stick calls up, may cause such change. Besides its feelings, the general and the organic movements of the dog are, like our own, governed by a multitude of organic influences which are not felt, but which operate through the nervous system, and so must be taken as parallel with those which are felt, *i.e.* as unfelt, nervous psychoses. The animal, then, like each of us, is a creature of activities partly physical, partly psychical, the latter—both the felt and the unfelt—being directive and controlling.

As we descend to the lowest animals, the evidence as to sentience fades. Yet from the resemblances of the lowest animals and plants, and from the similarity of the vegetative functions in all living creatures, we may, I think, analogically conclude that activities also take place in plants which are parallel with, and analogous to, the unfelt psychoses of animals. As Asa Gray has said with respect to their movements: "Although these are incited by physical agents (just as analogous kinds of movements are in animals), and cannot be the result of anything like volition, yet nearly all of them are inexplicable on mechanical principles. Some of them at least are spontaneous motions of the plant or organism itself, due to some inherent power which is merely put in action by light, attraction, or other external influences."

I have already adverted to insectivorous plants, such as *Dionæa*. In such plants we have susceptibilities strangely like those of animals. An impression is made, and appropriate resulting actions ensue. Moreover, these actions do not take place without the occurrence of electrical changes similar to those which occur in muscular contraction. Hardly less noteworthy are the curious methods by which the roots of some plants seek moisture as if by instinct, or those by which the tendrils of certain climbers seek and find appropriate support, and having found it, cling to it by a pseudo-voluntary clasping, or, finally, those by which the little "Mother-of-a-thousand" explores surfaces for appropriate hollows in which to deposit her progeny.

Nevertheless, nothing in the shape of vegetable nervous or muscular tissue has been detected, and as structure and function necessarily vary together, it is impossible to attribute sensations, sense perceptions, instincts, or voluntary motions to plants, though the principle of individuation in each acts as in the unfelt psychoses of animals and harmonises its various life-processes.

The conception, then, which commended itself to the clear and certainly unbiassed Greek intellect of more than 2,000 years ago, that there are three orders of internal organic forces, or principles of individuation, namely, the rational, the animal, and the vegetal,[1] appears to me to be justified by the light of the science of our own day.

I come now to the bearing of these remarks on the science of biology generally.

Animals and plants may, as I have before said, be regarded either *statically*, by anatomy, or *dynamically*, by physiology.

Physiology, as usually understood, regards the properties of the ultimate morphological components of organisms, the powers of the various aggregations of such components, *i.e.* of the various "tissues" and the functions of the different special aggregations and arrangements of tissues which constitute "organs."

But as each living creature is a highly complex unity—both a unity of body and also a unity of force, or a synthesis of activities—it seems to me that we require a distinct kind of physiology to be devoted to the investigation of such syntheses of activities as exist in each kind of living creature. I mean to say that just as we have a physiology devoted to the several activities of the several organs, which activities are the functions of those organs, so we need a physiology specially directed to the 'physiology of the living body considered as one whole, that is, to the power which is the function, so to speak, of that whole, and of which the whole body, in its totality, is the organ.

In a word, we need a *physiology of the individual*. This science, however, needs a distinct appellation. I think an adequate one is not far to seek.

Such a line of inquiry may be followed up, whatever view be accepted as to the nature of those forces or activities which living creatures exhibit. But if we recognise, as I myself think our reason calls on us to recognise, the existence in each living being of such a "principle of individuation" as I have advocated the recognition of, then an inquiry into the total activity of any living being, considered as one whole, is tantamount to an

b "a physical state." Then a sensation and its physical accompaniment may be represented by the symbol $a + b$. But a physical state is itself but a state of consciousness with its objective correlate, and is, therefore, $a + b$. We thus get an equation infinitely more erroneous than $b = a + b$, because the b of the $a + b$ is itself ever again and again $a + b$.

[1] As when having gazed vacantly through a window we revert to the pages of a manuscript we may be writing and see there the spectra of the window bars we had before unconsciously seen. Here the effect on the organism must have been similar to what it would have been had we attended to it—*i.e.*, it was unfelt sensation.

[1] Difficult as it confessedly is to draw the dividing line between animals and plants, such difficulty is not inconsistent with the existence of a really profound difference between the two groups. That there should be a radical distinction of nature between two organisms, which distinction our senses nevertheless, more or less fail to distinguish, is a fact which on any view must be admitted, since animals of very different natures may be indistinguishable by us in the germ, and in the earlier stages of their development. The truth of this is practically supported by the late Mr. Lewes, who says (as to the difference between the protoplasms from which animals and plants respectively arise): "That critical differences must exist is proved by the divergence of the products. The vegetable cell is not the animal cell; and although both plants and animals have albumen, fibrine, and caseine, the *derivatives* of these are unlike. Horny substance, connective tissue, nerve tissue, chitine, biliverdine . . . and a variety of other products of evolution or of waste, never appear in plants; while the hydrocarbons abundant in plants are, with two or three exceptions, absent from animals. Such facts imply differences in elementary composition; and this result is further enforced by the fact that when the two seem to resemble, they are still different. The plant protoplasms form various cells, but never form a cartilage cell, or a nerve cell; fibres, but never a fibre of elastic tissue; tubes, but never a nerve tube; vessels, but never a vessel with muscular coatings; solid "skeletons," but always from an organic substance (*cellulose*), not from phosphates and carbonates. In no one character can we say that the plant and the animal are identical; we can only point throughout the two kingdoms to a great similarity accompanying a radical diversity."—"The Physical Basis of Mind," p. 129.

inquiry into the nature of its principle of individuation. Such an inquire becomes "*psychology*" in the widest and in the original signification of that term—it is the psychology of Aristotle.

Mr. Herbert Spencer has already made a great step towards reverting to this original use of the term, for he has made his "psychology" conterminous with the animal kingdom, having made it a history of the psychoses of animals. But the activities of plants must not be ignored. A science which should include the impressionability and reactions of a Rhizopod and exclude the far more striking impressionability and reactions of Venus's fly-trap, and of other insectivorous plants, the recognised number of which is greatly on the increase, must be a very partial and incomplete science. If psychology is to be extended (as I think Mr. Spencer is most rational in extending it) to the whole animal kingdom, it must be made to include the vegetable kingdom also. Psychology, thus understood, will be conterminous with the whole of biology, and will embrace one aspect of organic dynamics, while physiology will embrace the other.

PHYSIOLOGY will be devoted (as it is now) to the study of the activities of tissues, of organs, and of functions, *per se*, such, *e.g.*, as the function of nutrition as exhibited in all organism from the lowest plants to man, the functions of respiration, reproduction, irritability, sensation, locomotion, &c., similarly considered, as manifested in the whole series of organic forms in which such powers may show themselves.

PSYCHOLOGY will be devoted (according to its original conception) to the study of the activities of each living creature considered as one whole—to the form, modes, and conditions of nutrition and reproduction as they may coexist in any one plant; to these, as they may coexist with sensibility and motility in any kind of animal, and finally to the coexistence of all these with rationality as in man, and to the interactions and conditions of action of all these as existing in him, and here the science which corresponds to the most narrow and restricted sense of the word, psychology, *i.e.*, the subjective psychology of introspection, will find its place.

Psychology in the widest sense of the term, in its oldest and in what I believe will be its ultimate meaning, must necessarily be, as to its details, a science of the future. For just as physiology requires as a necessary, antecedent condition, a knowledge of anatomy—since we must know that organs *exist* before we investigate what they *do*—so psychology requires as a necessary, antecedent condition, an already advanced physiology. It requires it because we must be acquainted with the various functions before we can study their synthesis and interactions.

When, however, this study has advanced, one most important result of that advance will be a knowledge, more or less complete, of the innate powers of organisms, and therefore of their laws of variation. By the acquisition of such knowledge we shall be placed in a position whence we may advance, with some prospects of success, to investigate the problem of the "origin of species"—the biological problem of our century.

This reflection leads me back once more to my starting-point, the merits of the great French naturalist of the last century, whose views as to variation and as to animal psychosis, have enabled me to bring before you the questions on which I have presumed to enter. Buffon's claims on our esteem have, I think, been too much forgotten, and I rejoice in this opportunity of paying my debt of gratitude to him by recalling them to recollection. As to the questions which his words have suggested to me and upon which I have thus most imperfectly touched, the considerations I have ventured to offer may or may not commend themselves to your approval; but, at least, they are the result of not a few years of study and reflection, and I am persuaded they have consequences directly or indirectly affecting the whole field of biological inquiry, which belief has alone induced me to make so large a call upon your patience and your indulgent kindness.

NOTES

AMONGST other lectures announced for the coming Baden-Baden meeting of the German Association of Naturalists, to which we have not referred in our note last week, we may mention that at the opening of the first general meeting on September 18, Prof. Kussmaul, of Strasburg, will deliver a memorial address in memory of the late Dr. Benedict Stilling, of Cassel, the first secretary of last year's meeting. The second and third general meetings will take place on September 20 and 24 respectively, and will be partly occupied with the following lectures:—Prof. Ecker, of Freiburg, "On Lorenz Oken, in connection with the Centenary of his Birth;" Prof. Goltz, of Strasburg, "On the Heart;" Prof. Jaeger, of Stuttgart, "On Affections of the Mind." The sectional meetings will take place on September 19, 22, and 23. For these up to the present no less than seventy-six papers have been announced, comprising all domains of natural science and medicine. The following may be of more general interest:—"On the Colour Sense among the Ancients and among Modern Uncivilised Tribes," by Prof. Hartmann, of Berlin; "On the Injurious Effects of the Refuse of Factories, specially of Bleaching Works, with regard to Fish," by Dr. Weichelt, of Rufach; "On the Physiology of the Brain," by Prof. Goltz, of Strasburg; "On Sea Climates and Sea Voyages, from a Physiological and Pathological Point of View," by Dr. Faber, of Stuttgart; "On Crimes and Insanity," by Dr. Kornfeld, of Wohlau; "Experimental Lecture on the Brain," by Prof. Rüdinger, of Munich; "On the Present State of Animal Vaccination and the Corresponding Institutions in Germany, Holland, and Belgium," by Dr. Fürst, of Leipzig.

THE Sanitary Congress and Exhibition of the Sanitary Institute of Great Britain will this year be held at Croydon. Dr. Richardson, F.R.S., has accepted the office of President of the Congress, and a large and influential committee, of which Mr. John Corry is the chairman, has been formed. The Sanitary Congress is divided into three sections, viz.:—Section 1.—Sanitary Science and Preventive Medicine; president, Alfred Carpenter, M.D., London, J.P. Section 2.—Engineering and Sanitary Construction; president, Capt. Douglas Galton, R.E., C.B., F.R.S. Section 3.—Meteorology and Geology; president, G. J. Symons, F.R.S. Arrangements have also been made for one or more lectures, one of which will be delivered by Prof. Corfield.

THE Fourth Annual General Meeting of the Mineralogical Society of Great Britain and Ireland, to receive the Report of the Council, and elect Officers for the ensuing year, and for general business, will be held at the Freemasons' Hall, Surrey Street, Sheffield, on Friday, August 22, at 3 P.M. The following papers will be read:—"On the Production of Different Secondary Forms of Crystalline Minerals," by H. C. Sorby, F.R.S.; "New Scottish Minerals," by Prof. M. F. Heddle; "On some Cornish Serpentinous Rocks," by J. H. Collins, F.G.S.

THE Fifth Annual Conference of the Cryptogamic Society of Scotland will be held at Forres, on September 17 and following days. The programme of arrangements has been garnished with several not inappropriate quotations from Shakespeare, whose "Macbeth" is naturally suggested by Forres.

DR. JOHN M'KENDRICK, Professor of the Institutes of Medicine in Glasgow University, has been appointed Lecturer in Natural Science and Theology for Session 1879-80, under the Banchory Bequest, at Aberdeen Free Church College, in succession to Dr. Lauder Brunton.

WE regret to record the death of Sir Thomas Moncreiffe of Moncreiffe, Bart., President of the Perthshire Society of Natural Science, and late President of the Cryptogamic Society of Scotland. Sir Thomas was an enthusiastic entomologist and did much to foster and promote the study of natural history in Perthshire. Amongst the schemes which he had at heart was the establishment of an efficient local museum and other aids to the promotion of the study of science in Perth. He was a frequent contributor to the pages of the *Scottish Naturalist*, among his latest contributions being a catalogue of the lepidoptera observed within one square mile at Moncreiffe, which included no less than upwards of 600 species, and is valuable for the notes on

the habits and for the light thrown on the geographical distribution of the species in Britain. Sir Thomas, who was Vice-Lieutenant of Perthshire, died on August 16, in his fifty-seventh year.

THE death is announced of Dr. Immanuel Hermann von Fichte, formerly Professor of Philosophy at Bonn and Tübingen Universities, and son of the celebrated Jena professor. Dr. von Fichte was born at Jena in 1797, and died at Stuttgart on August 8 last.

THE fifth Russian Archæological Congress will be held at Tiflis in September, 1881, and will be specially devoted to the investigation of ancient monuments. A committee meeting will take place at Moscow in January, 1880, when the detailed programme of the Congress will be arranged.

IN one of the recently submerged coal mines in the Dux district (Bohemia) a remarkable phenomenon has occurred which Dr. Braumüller, an eminent Austrian mining engineer, describes. It appears that in the subterranean waters of the "Fortschritt" mine regular tides have been observed for the last six months. Both the Berlin and the Vienna Academies of Sciences, are devoting considerable attention to the strange phenomenon. A satisfactory explanation has, however, not yet been arrived at by either.

THE electric light has made its way to the highest hotel of Europe, *i.e.*, to the hotel which is situated at the greatest elevation above the sea-level. The "Engadiner Kulm" Hotel at St. Moritz, in the Upper Engadine, boasts of an elevation of 1,856 metres above the sea, and the proprietor announces that the establishment now possesses eight Jablochkoff lamps. A waterwheel is the motor of the electric machine feeding the lamps.

THE National Water-Supply Exhibition was inaugurated at the Alexandra Palace last Thursday by the Lord Mayor; Mr. Chadwick, C.B., Col. Bolton, Mr. Wanklyn, Prof. Seeley, and others interested in the water-supply question, were present at the luncheon. The exhibition, which covers a wide and varied field of appliances and products in connection with the supply and uses of water, is really interesting, and ought to attract the attention of visitors. We trust it will have the educational effect hoped for. It is intended to keep it open till the spring, and as the object is to collect information as well as to spread it, it is hoped that those who have any maps, or tables referring to water-supply, will send them. Information respecting the aims of the committee may be obtained from Mr. A. T. Atchison, M.A., 34, Great George Street, Westminster. From the remarks of Mr. Cross on Mr. Fawcett's motion last week, it would seem as if Government had determined to deal with this all-important question.

THE Giffard monster captive balloon burst on the 16th inst., a little before six o'clock, when a moderate wind was blowing from the south-east. It will be remembered that M. Henri Giffard placed his balloon in the hands of a company of uneducated aëronauts, who neglected to follow his advice, and for economy's sake left his balloon partly uninflated. The wind acting on the vacuum left in the lower part of the balloon, agitated the canvas in so extraordinary a manner that it gave way. It will not be restored this year, the season being too far advanced for the purpose.

THE French Academy of Meteorological Ascents made two successful experiments, one at St. Germain on the 9th inst., and the other at Cambrai, to test whether it was possible to prognosticate, with the help of pilot balloons, the path which the mounted aërostat would follow. The results were satisfactory. At St. Germain the wind was very light and uncertain, but at Cambrai the velocity was forty kilometres an hour. A competent colombophile had been placed in the car, and a number of carrier-pigeons were liberated from the balloon, and a narrative of the principal incidents of the journey was posted in the city before the aërial travellers had landed. The system had been explained by M. de Fonvielle in a lecture given in the morning in the town-hall.

THE correspondent of a Swiss paper warns collectors of antiquities to beware of fabricated specimens of articles purporting to belong to the age of bronze and to have been found among the remains of lake dwellings and in the beds of rivers. He says there is a regular manufactory of these things near the Lake of Bienne, and that bronze swords are being offered at 100f. each which are not worth as many centimes.

TWO streams of lava flowed on the 15th from Mount Vesuvius to the base of the cone. There was no eruption on the 16th.

M. MOREL FATRO, who is conducting some extensive explorations at the lacustrine station of Corcelettes, Canton Vaud, announces the discovery of a large canoe in an excellent state of preservation. It is formed of a single pine log 32 feet long and 2¾ feet wide; and though the stern is slightly damaged, the bow, which is carved and ornamented, is perfect. This interesting find will be placed in the museum of Lausanne, which now contains the richest collection of lacustrine relics in Europe.

THE new part of the *Transactions* of the Asiatic Society of Japan contains much interesting matter; the most important paper, however, is one on the transliteration of the Japanese Syllabary, by Mr. Ernest M. Satow, of H.M.'s Legation at Yedo, who has industriously applied himself to the study of the language for the past eighteen years, and is one of the greatest authorities on the subject. There are also two papers worthy of notice, the one on inscriptions in Shimabara and Amakusa, and the other on the foreign travel of modern Japanese adventurers.

A PARTY recently visiting the Daly River, North Australia, appear to have met with an alligator far larger than any hitherto seen. Nothing but the head was visible, but this is described as being about 4 feet in length and 2 feet 6 inches in width. On being fired at the monster disappeared, and the precise size of its body could not be ascertained.

IN a valley at the foot of the so-called Habichtswald, near Cassel, a short distance from the castle of Wilhelmshöhe, a new ferruginous mineral spring has been discovered. The water of the new spring belongs to the class of alkaline earthy iron-waters, and besides salts of iron, contains a great quantity of carbonate of lime. It strongly resembles the Schwalbach waters both in taste and composition.

THE Government of Western Australia has offered a reward for the discovery of new guano islands. Valuable deposits are believed to exist on the north coast between the Lacepedes and Camden harbour.

MR. WM. HUGHES'. "Outlines of Geology and Geological Notes of Ireland" has reached a third edition, which the author states has been almost rewritten. It contains a considerable number of illustrations. Gill and Son of Dublin are the publishers.

"THE Students' Catalogue of British Plants, arranged according to the Students' Flora of the British Isles, by Sir J. D. Hooker, C.B.," is the title of a useful list, compiled by the Rev. George Henslow, and published by Bateman, of Portland Town, London.

THE *Proceedings* of the Bristol Naturalists' Society contains as usual several excellent papers. Mr. Stoddart's papers on the geology of the Bristol coal field are continued; Mr. Bucknall contributes a list of the fungi of the Bristol district; Dr. Fripp an account of some experiments on insect hearing; Mr. A. E.

Hudd part 2 of a catalogue of the Lepidoptera of the Bristol district.

"SCIENCE Teaching in Living Nature, a Popular Introduction to the Study of Physiological Chemistry and Sanitary Science," is the title of a little volume by Mr. W. H. Watson, F.C.S., just published by Stanford.

THE additions to the Zoological Society's Gardens during the past week include two Diana Monkeys (*Cercopithecus diana*) from West Africa, presented by Mr. F. J. Crocker; a Green Monkey (*Cercopithecus callitrichus*) from West Africa, presented by Mr. C. F. S. Day; a Malbrouch Monkey (*Cercopithecus cynosurus*) from West Africa, presented by Miss Agnes Barker; a Black Stork (*Ciconia nigra*) from Jutland, presented by Prof. J. Reinhardt, F.M.Z.S.; a Rose-crested Cockatoo (*Cacatua moluccensis*) from Moluccas, presented by Miss Foster; fourteen Golden Tench (*Tinca vulgaris*, var.), presented by Lord Walsingham, F.Z.S.; a Common Buzzard (*Buteo vulgaris*), European, deposited; two Black-footed Penguins (*Spheniscus demersus*) from South Africa, purchased; two Crested Pigeons (*Ocyphaps lophotes*), two Geoffroy's Doves (*Peristera geoffroii*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN

THE ELONGATED NEBULÆ.—The amateur provided with an equatorial of fair aperture and a parallel-wire micrometer might do good service by the accurate determination of the angles of position of the elongated or greatly-extended nebulæ, of which so far the number of reliable measures is but small, though such objects are pretty commonly distributed. The necessity for further observations in this direction is well illustrated by the note to No. 2501 of Sir John Herschel's General Catalogue = H. I. 94; H. made the nebula by one observation extended n. to s., by another nf. to sp., while two observations by Sir John Herschel agree in making it extended in the parallel; "Surely," he remarks, "it does not rotate?" D'Arrest ("Siderum Nebulosorum") merely says: "Circa directionem axis nihil annotatum fuit."

In 1874 Mr. Cleveland Abbe called attention to this subject, and in the *American Journal of Science and Arts*, January, 1875, has collected the approximate places of about sixty elongated nebulæ from Herschel's catalogue, and has appended formulæ by which the right ascension and declination of the poles of a very much extended nebula may be calculated. These formulæ he has applied to such measures or estimations, often rough ones, of the angles of position as were then published.

THE NEW BINARY STAR τ CYGNI.—This star, the duplicity of which was detected by Mr. A. G. Clark in October, 1874, with the 26-inch object-glass manufactured for Mr. McCormick, of Chicago, well deserves following up; in the $3\frac{1}{2}$ years to 1878·4, when measures were made by Mr. Burnham, the angle of position had retrograded 25°, with but little change of distance, though a slight decrease may be suspected. The components are about 4·5 and 8. Right ascension for 1880, 21h. 10m. 8s.; declination, 37° 32'. If the motion in angle has been equable since 1874, the position may now be about 140°.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

"Report of an Unusual Phenomenon Observed at Sea"

As the unusual phenomena observed in the Persian Gulf, described in NATURE, vol. xx. p. 291, has hitherto called forth no remarks, I venture to put forward a suggestion that may be of service in elucidating the matter.

First, I would observe that the so-called parallel waves were probably arcs of large concentric circles, whose common centre lay south-south-west of H.M.S. *Vulture's* first, and east of her last, position. The distance between these positions was about a knot and a half, therefore the vessel was never nearer this centre than about half a mile, and a short arc of a circle of this radius might well be deemed straight.

The accompanying diagram, drawn from the data, shows the position of the centre of disturbance, and of the luminous waves, with relation to the course of the ship, taking the above view, which I think is borne out by the character of the second series of luminous waves through which H.M.S. *Vulture* passed.

Most living creatures possessing phosphorescence have more

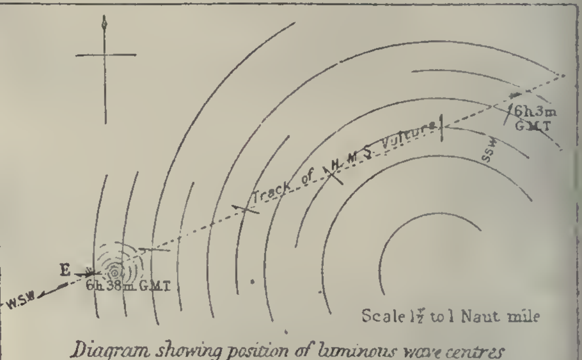

Diagram showing position of luminous wave centres

or less control over its display. In the case of the fire-fly, the light that one emits calls forth almost instantaneously answering flashes from others. No dweller in the tropics can have failed to observe the manner in which trees are lit up by the simultaneous flash of thousands of fire-flies, and the period of darkness that intervenes before the next flash. If then we consider the *Vulture* to have passed through a shoal (if I may so term it) of animalculæ, possessing the power of exhibiting phosphorescence intermittently, and exciting each other to do so, the impulse travelling from one to another at the rate of 125 feet a second, and the display of light to the dark interval bearing the ratio 1 to 3 (in time, $\frac{1}{4}$ of a second to $\frac{3}{4}$), we have accounted for the phenomena so far as the luminous waves are concerned.

What were the central disturbances that originated the action, it is impossible to say, though it is easy to imagine several causes of irritation, that would not have been detected by the simple observations taken on board the vessel.

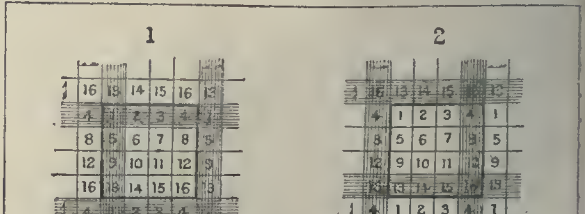

Diagram showing intersections of luminous waves.

The luminous waves of the smaller series "meeting the parallel waves from south-east did not cross, but appeared to obliterate each other at the moving point of contact." The above is difficult to explain, if the luminosity of the waves was obliterated at the actual intersections. It can however be readily shown that close to the intersections are spaces where the phosphorescence of the animalculæ would have to be displayed for twice as long a period as in other positions, and we have but to admit a want of energy to meet this call, and dark spaces will appear in each system of waves, immediately following the passage of the crossing wave.

This would certainly give the appearance of one wave obliterating the other.

A second diagram explains this simply. Here a portion of ocean is divided into numbered squares of 25 feet, and the advance of the 25′ luminous waves, 75′ apart is shown in two following positions. It will be seen that spaces numbered 4 and 13 fall successively under the impulses. Similarly, in the next 25′ advance of the waves, would all those numbered 12 and 15, and so on, the assumed dark spaces following in the wake of each intersection, as it pursues its diagonal course.

Beckenham, August 5 EDWARD H. PRINGLE

The Planet Jupiter

IN the bright zone south of the south equatorial belt may now be seen a strange and beautiful feature like a flame—red elliptical cloud surrounded by a brilliant white aureole. I first observed it near midnight on the 14th inst., when approaching the middle of its apparent course across the disk.

In November, 1869, Mr. Gledhill discovered an elliptical figure in the same zone, but it was dark, with an interior space bright and colourless.

Gledhill's No. 2 belt (*Ast. Register*, April, 1870), which was a most striking feature for some years, disappeared in 1874, re-appeared in May, 1875, again disappeared, and is now again faintly visible. It is *under* (north of) the north equatorial belt.

The south equatorial belt seems of a slate-blue, the north of a russet or dark red colour. The bright central space is crossed by dark, irregular bridges slanting from south-west to north-east—the invariable direction of all the oblique formations that I have ever remarked on Jupiter.

The north polar region seems occupied by a number of apparently close, narrow belts. The south has a pretty similar appearance, but the belts here are not so numerous nor so distinct. JOHN BIRMINGHAM

August 15

Twenty-nine Gleams of Sunshine, August 7, 8, 9, in Nine Hours

IN a paper, about weather, written by Mr. Ellis, of Greenwich Observatory, and published in NATURE, vol. xx. p. 313, mention is made of work done with an instrument for registering sunshine, which I contrived, got made, and gave to the Observatory. It consists of a glass sphere, a stand for it, and a metal bowl. The spherical surfaces have a common centre, and radii so measured that the focal cone of sunshine condensed by the glass is cut, by blackened cardboard fixed in the bowl, at the same distance, and at right angles, whatever the sun's position may be in the visible sky. The temperature near the point is at least 700° when the weather is clear. The sun's circular image describes a circle about the common centre, and it burns a trace on cardboard when the sun shines clearly. I can think of nothing better or simpler for the purpose of registering sunshine and counting clouds daily.

The inclosed printer's block was engraved in the focal cone of a cast glass sphere. The flat surface, blackened with shoe-blacking, was set roughly parallel to the plane of the equator, and the hot point was brought to bear upon it, at about 1 P.M. on August 7. Thus arranged the section of the cone is not circular, but is an ellipse, which is longer or shorter in proportion to the clearness of the atmosphere. The ellipse describes a circle on the boxwood plane. Hollows burned out by it print white, the surface left prints black. Clouds which crossed the sun's path may be counted between white oval spots. There are twenty-nine spots, the rest was cloud. In common weather parlance the morning of the 7th was "sunny," but the blue sky was veiled by a broken roof of thin detached clouds, moving eastward. They hindered heat waves. Between them were narrow clearer openings. When one of these passed the sun the cone of sunshine burned the block instantly. Afternoon about two, the broken cloud roof mended, rain fell, and the evening was dark and sunless. The night was wet. The morning of the 8th was "cloudy." Not a patch of blue sky was visible big enough to make a pair of breeches for a Dutchman. But the weather "looked as if it might clear up." The sun was "trying to shine." Birds sung notes which forecast a fine day,

2 P.M. 10 A.M.

and the day was "fine." The official forecast was "cloudy" and the day was very cloudy. The sun was seen "wading through mist" at intervals. At 10 A.M. one brighter gleam burned a mark; but that was all the bright sunshine that reached this garden. For a great depth the air was full of water condensed into the shape of the burning glass. Each spherical drop acted on sunshine as the bulb of a spirit thermometer acts—in "absorbing heat," in stopping, refracting, and dispersing waves of solar radiation. There was more shade than sunshine at the ground. The morning of the 9th was sunny, hazy, and cloudy. But large patches of very pale blue sky were visible. Birds foretold a fine day, and they were true prophets. The sun's image came on the block at 9.30 A.M., and it was set carefully at 10, and left till 2 P.M. The air was "thick" all day, the blue of the sky was very pale, and the sunshine "watery." The record shows when brighter gleams occurred during the time of exposure. About noon, as commonly happens, clouds gathered and hid the sun. The brightest time came after noon.

This bit of "thermographic wood engraving" may give readers in brighter climes some notion of the dismal cloudy sky of this abnormal English summer. There has not been a cloudless day since the year began. The blue of the sky never has been the dark indigo of Egyptian and Californian skies.

The cause of this excess of cloud I take to be excess of solar radiation, and consequent evaporation to our westward. Condensation has been in proportion along the European Atlantic coasts, where the ground was chilled by a late and severe winter, and has been little warmed and dried since by sunshine. According to casual and official weather reports, public and private, the heat has been great in America, on the Atlantic, in Spain, in the south of France, in Eastern Russia, in Egypt, and on the Red Sea. The sun shines fiercely upon the ground beyond the edge of a great cloud which has come persistently from the Western Ocean to overshadow our islands, and to drench and batter them with rain and hailstones. Our shadow is the result of sunshine. Our grass is green, our health is good, our gardens are gay in spite of the clouds, or because of them.

Believing in this theory I am going eastward in search of brighter weather, and I send this record of watery sunshine for your acceptance before I start. J. F. CAMPBELL

Niddry Lodge, Kensington, August 9

Electric Clocks

THE various contrivances for electric clocks all depend on producing contacts with the pendulum, which is confessedly undesirable; and they nearly all produce these contacts when the pendulum is at rest at the highest point, which is the worst position.

There seems no reason why a pendulum with a coil-bob traversing over a short permanent magnet, as is usual, should not be independent of contacts. While descending the lower part of the stroke it reaches the magnet, and a current is thus excited in the coil, which is conveyed out at the knife-edges and works a switch; this sends a battery current through the coil for a short period while the pendulum is beginning its ascent, and so drives it forwards by repulsion from the magnet. The same process is repeated in the back stroke. The interval between the production of the excited current and the battery current, and also the duration of the battery current, may be regulated by a small pendulum whose single swing is equal to the interval, and which is liberated by the excited current. The details are so easily

arranged that it is scarcely worth while to particularise them. Of course the battery current thus liberated by the excited current could be used for controlling other clocks.

The effect on the pendulum is thus restricted to the quicker parts of its swing; and consists of slightly retarding the descent, and accelerating the ascent, apart from all mechanical friction or contacts. Thus each action is produced at the most suitable time.

Possibly a pendulum cutting off heat rays from a thermopile might thus work a switch, and be even less affected than by producing an excited current in the coil-bob, as proposed above.

Bromley, Kent W. M. FLINDERS PETRIE

Did Flowers Exist during the Carboniferous Epoch?

NOTICING in your pages under the above heading a discussion on *fossil* butterflies and moths, &c., and being struck with the deep interest taken in the question as evidenced by the letter of the Rev. A. E. Eaton (vol. xx. p. 315), I thought that I would ask for a very small space for an intercommunication which may forward investigation.

I have in my collection what appears to me to be a butterfly (using the word without any regard to scientific nomenclature), as a carbonaceous impress on a piece of shale from the Slievardagh coal-field, Tipperary; and by way of contributing my mite towards an inquiry which it gives me pleasure to find so earnestly pursued, I shall be happy to forward the specimen for examination to any of the scientific gentlemen interested who will furnish me his address, or in turn to as many as it will be convenient so to accommodate, on *condition that the specimen be returned to me in good order and without unreasonable delay*.

I may be allowed to add that I have no sympathy whatever with the discussion in its present bearings.

Earlshill Colliery, Thurles, August 7 WILLIAM MORRIS

"Euclid and His Modern Rivals"

MR. DODGSON thinks "it worth while to point out a mistake made in the paragraph about Mr. Morell's book" (NATURE, vol. xx. p. 240). In the words "the thing not being capable of proof," the "thing" referred to is Mr. Morell's assertion that "the perimeter *MDQRSTM* is less than the perimeter *MPQRSTM*," which is not necessarily true, and of course is incapable of proof. Surely this assertion, which I quote two lines before "thing" occurs, is its grammatical antecedent? *You* refer it back to the theorem itself, which Mr. Morell is trying to prove—a theorem which *is* true and easily proved." I gladly accept Mr. Dodgson's statement, which is, if I remember rightly—for I am here far away from Mr. Dodgson's book—perfectly correct—and apologise for having inaccurately represented his meaning.

THE WRITER OF THE NOTICE OF "EUCLID AND HIS MODERN RIVALS"

SOCIETIES AND ACADEMIES

LONDON

Entomological Society, August 6.—J. W. Dunning, M.A., F.L.S., vice-president, in the chair.—Mr. Philips exhibited living specimens (both sexes) of *Spercheus emarginatus*, taken at West Ham.—Mr. Stainton exhibited, on behalf of Mr. Grigg, of Bristol, larvæ of *Rösterstammia erxlebella*, a genus of which the larva had hitherto been unknown.—Miss Ormerod read a paper entitled "Sugar-cane Borers of British Guiana," and exhibited specimens of the insects referred to, in different stages of development. The exhibition was made on behalf of the Colonial Company, who were anxious to receive any information as to available and practical methods of dealing with these insects. Mr. Distant stated that the circumstances were almost the same on the sugar estates in the Straits Settlements at Malacca, where burning the infected canes was the usual remedy applied.—Mr. Swinton communicated a note with reference to the urticating properties of the larva of *Liparis auriflua*, and a communication was also received from Mr. McLachlan on correlation of mutilation in the larva with deformity in the imago, being the substance of a notice by M. Melise on the subject in the *Compte Rendu* of the Belgian Entomological Society.

THE BRITISH ASSOCIATION AT SHEFFIELD

THE Forty-ninth Annual Meeting of the British Association must be reckoned one of decided success. The large number and variety of papers read in the sections, the excellence of presidential and sectional addresses and of evening discourses, the satisfaction afforded by local and general arrangements, and not least by the favourable meteorological conditions prevailing during the week, have all contributed to make the Sheffield gathering one to be remembered with pleasure.

The president, Dr. Allman, had the misfortune at the outset to be suffering from a severe cold, which made the delivery of his admirable address somewhat laboured and painful. But his audience proved sympathetic and even enthusiastic; and the printed copies of his address have been eagerly demanded on all hands. Whether prepared to agree with the dictum that irritability as a property of matter is the one grand characteristic phenomenon of all living things, or not, none will dispute the extreme ability and lucidity of the address.

Surprise has been expressed in some quarters that Prof. Allman should have ventured to found such momentous speculations, even partly, on so unstable a basis as "Bathybius," and in this connection Prof. Huxley's remarks in supporting the vote of thanks to the president are well worth reproducing:—

"It is my business to recollect, on the present occasion, that I have come to praise Cæsar, and not to bury him under any mountain of talk of my own; and I will, therefore, not venture to dwell upon any of those very large topics upon which he has dwelt with so much fairness, with so much judgment, and with so remarkable a knowledge of the existing information respecting them. But I will ask you to allow me to say one word rather on my own account, in order to prevent a misconception which, I think, might arise, and which I should regret if it did arise. I dare say that no one in this room, who has attained middle life, has been so fortunate as to reach that age without being obliged now and then to look back upon some acquaintance, or, it may be, intimate ally of his youth, who has not quite verified the promises of that youth. Nay, let us suppose he has done the very reverse, and has become a very questionable sort of character, and a person whose acquaintance does not seem quite so desirable as it was in those young days; his way and yours have separated; you have not heard much about him; but eminently trustworthy persons have assured you he has done this, that, or the other; and is more or less of a black sheep, in fact. The president, in the early part of his address, alluded to a certain thing—I hardly know whether I ought to call it thing or not—of which he gave you the name Bathybius, and he stated, with perfect justice, that I had brought that thing into notice; at any rate, indeed, I christened it, and I am, in a certain sense, its earliest friend. For some time after that interesting Bathybius was launched into the world, a number of admirable persons took the little thing by the hand, and made very much of it, and, as the president was good enough to tell you, I am glad to be able to repeat and verify all the statements, as a matter of fact, which I had ventured to make about it. And so things went on, and I thought my young friend Bathybius would turn out a credit to me. But I am sorry to say, as time has gone on, he has not altogether verified the promise of his youth. In the first place, as the president told you, he could not be found when he was wanted; and in the second place, when he was found, all sorts of things were said about him. Indeed, I regret to be obliged to tell you that some persons of severe minds went so far as to say that he was nothing but simply a gelatinous precipitate of slime, which had carried down organic matter. If that is so, I am very sorry for it, for whoever else may have joined in this error, I am undoubtedly primarily responsible for it. But I do not know at this present time of my own knowledge how the matter stands. Nothing would please me more than to investigate the matter afresh in the way it ought to be investigated, but that would require a voyage of some time, and the investigation of this thing in its native haunts is a kind of work for which, for many years past, I have had no opportunity, and which I do not think I am very likely to enjoy again. Therefore my own judgment is in an absolute state of suspension about it. I can only warn you what has been said about this friend of mine, but I cannot say whether what is said is justified or not. But I feel very happy about the matter. There is one thing about us men of science, and that is no one who has the greatest prejudice against science can venture to say that we ever endeavour to conceal each other's mistakes. And, therefore, I rest in the most entire and complete confidence that if this should happen to be a blunder of mine, some day or other it will be carefully exposed by somebody. But pray let me remind you whether all this story about Bathybius be right or wrong makes not the smallest difference to the general argument of the remarkable address put before you to-night. All the statements your president has made are just as true, as profoundly true, as if this little eccentric Bathybius did not exist at all. I congratulate you upon having had the opportunity of listening to an address so profound, so exhaustive in all respects, and so remarkable, and I ask you to join in the vote of thanks which has just been proposed."

A clever metrical skit on the president's address by an eminent geologist caused considerable amusement to those who had the privilege of seeing it.

The first of the evening discourses was by Mr. W. Crookes, F.R.S., upon Radiant Matter, and was illustrated by a unique display of those exquisite experiments on the movements of molecules in high vacua which have recently attracted so much attention. Nothing could exceed the beauty or brilliance of the experiments, which were made on a scale sufficiently large to be visible to an audience of nearly two thousand persons. The final experiment of allowing the air to enter through a microscopic hole into an exhausted radiometer bulb of large dimensions afforded the lecturer the means of making a most telling illustration of the enormous figures which must be employed in calculating the numbers of molecules contained in a small space.

The second discourse, by Prof. Ray Lankester, F.R.S., on Degeneration, was an attempt to establish that the laws of organic evolution may work downwards as well as upwards, reducing a free crustacean to a barnacle, or a vertebrate to an ascidian: a view which may at least claim some antiquity on its side since it is but an expansion of the Koran legend of Moses and the men of the Dead Sea who degenerated into apes.

The Saturday evening lecture by Mr. W. E. Ayrton, upon the Transmission of Power by Electricity, was listened to by a crowded audience, a large proportion of whom were working men, and was illustrated experimentally on a large scale.

In the sections much good work has been done. Section A (Mathematics and Physics) has been remarkable for the absence of great names, yet it has been well attended on the whole. A paper on Etherspheres as a *vera causa* in Natural Philosophy, by Rev. S. Earnshaw, has deservedly attracted attention as giving forth a most ingenious speculation on the mechanics, so to speak, of

the relation between matter and energy. Mr. Gordon exhibited a number of beautiful and newly-devised instruments for his researches on electrical induction, and M. Janssen on two occasions brought forward some of the further results gleaned in the field of astronomical physics, in which his name is so justly renowned. A paper by Prof. H. A. Newton, of Yale College, on the Direct Motion of Periodic Comets of Short Period, presented many points of the highest interest, and is a most valuable contribution to theoretical physical astronomy. The President of the Section, Mr. Johnstone Stoney, F.R.S., communicated several valuable papers on Molecular Physics and on Spectroscopy. Dr. Graham reported some excellent observations on Atmospheric Electricity from Madeira; and Prof. S. P. Thompson dealt with the Retardation of Phase of Vibrations in the Telephone, and showed an instrument called the pseudophone, for producing acoustic illusions.

In the Department of Mathematics, which sat on Saturday morning, several important communications were made.

In Section B (Chemistry) Prof. Dewar presided, and contributed several papers. His address was solely concerned with industrial chemistry, and does not seem to have contained much of novelty. Naturally, metallurgy has claimed prominence in this industrial centre, and chemical visitors have had ample opportunity of visiting the various works in the neighbourhood. Amongst the establishments which have thus drawn large numbers of visitors are the Bessemer steel works of Messrs. Steel and Tozer, and the electroplating factory of Messrs. Walker and Hall.

The Biologists and Anatomists have kept Section D a centre of attraction. The addresses of Prof. Mivart and Dr. Pye-Smith are each admirable; and the quiet but effective sarcasm with which the latter exposed the fallacies of anti-vivisection agitators drew hearty applause. Dr. Tylor's address to the Department of Anthropology was no less interesting, and was listened to attentively, as were Sir J. Lubbock on Fruit and Seeds, and Dr. Crichton-Browne on the Influence of Domestication on Brain-Growth.

Section E (Geography) has been favoured by the presence of several distinguished travellers, Commander Cameron, Major Serpa Pinto, and Count S. de Brazza, all African explorers of note, having given papers. Afghan and Zululand have furnished themes of burning discussion to this Section.

The Economic Section appears to have taken a new lease of active life, and has seldom presented more animation.

In the Mechanical Section the subjects of Friction at High Velocities, the Patent Laws, Hot Air Blast, and Electric Lighting, have claimed attention, and M. Bergeron explained the principles of Francy's Fireless Locomotive.

In spite of the drawback of bad and inconvenient streets and poor hotel accommodation, the Association has been fairly accommodated, and the reception accorded has been most hearty. The Mayor, the Master Cutler, and many other citizens of prominence, have been unremitting in their efforts; and the praises of Yorkshire hospitality are loudly sung. The reception of the Mayor at the *soirée* of Thursday evening in the Cutlers' Hall was very brilliant. The scientific *soirée* of Tuesday evening was no less successful, though the pleasure of the occasion was at one moment threatened by an unfortunate difference of opinion between local and general authorities on the subject of dancing, concerning which, however, a compromise was subsequently arranged.

The Mayor's banquet on Saturday evening was attended by about 340 guests, and was highly successful. Mr. Mundella, in replying to the toast of the Houses of Parliament, proposed by Dr. Odling, deplored the lack of sympathy between Parliament and science, and declared that he had sat up late so often in support of the Ancient Monuments Bill of Sir J. Lubbock, that he had almost become an ancient monument himself. The Archbishop of York responded for the Clergy, and General Thuillier and Commander Cameron for the Army and Navy. Dr. Haughton, of Dublin, was as amusing as ever in proposing the health of the Presidents of Sections.

Many little excursions have been organised during the week to places of interest. The Saturday excursions were eminently successful, and the Thursday excursions, including expeditions to the Peak, Castleton, &c., were very popular and largely attended.

The reports of the sectional proceedings in the local papers seem to us unusually meagre, though the space devoted to the Association both in provincial and in London papers becomes each year increasingly great. The *Times* alone this year has had several leaders on the Association generally, as well as on the principal addresses, and it is gratifying to notice the decided improvement not only in the knowledge displayed in these articles, but also in the attitude of the leading paper towards science. In a somewhat hysterical article on Prof. Allman's address, the *Observer* of last Sunday seems to forget that science has all sorts of followers, and that the real workers rarely come before the public. Notwithstanding the apparently complete ignorance of the writer in the *Observer* as to what science really is, we cannot help agreeing with much that he says as to the present condition of the Association, and the urgent need of reform in its method of work, if it is not rapidly to degenerate into a "scientific garden party."

It is gratifying to notice the change of attitude of the Archbishop of York towards science and its followers, to judge both from the sermon of Sunday and his speech at the Mayor's banquet. He evidently no longer regards the foremost of the workers in science as emissaries of the "Evil One," but rather as fellow-workers with "the Church" for the highest good of humanity. To those who heard, on a Sunday, years ago, Prof. Huxley's famous address in Edinburgh, on the Physical Basis of Life, and the introductory references to an address delivered a few days previously by the Archbishop, this change of attitude must be very significant.

A committee was appointed last year for the consideration of the organisation of the Natural History Museum in connection with its removal to South Kensington. A memorial was forwarded by the Council to the First Lord of the Treasury, who could not receive a deputation, but who forwarded a reply.

The memorial referred to the fact that the Royal Commission on Science had recommended that the occasion of the removal of the collections to South Kensington New Museum be taken advantage of to effect a change in the official administration of that division of the British Museum; that a director of the collections and a board of visitors be appointed. The memorialists stated that notwithstanding these expressions of opinion, an Act had been passed by Parliament for the removal of the collection to South Kensington, but no change had been made in the mode of the administration. They called attention to the fact that it was at variance with the recommendations of the Royal Commissioners, and urged upon her Majesty's Government to take steps to carry out these recommendations, as the administration of the collections was of the utmort importance to the future progress of natural history in this country.

Capt. Douglas Galton read at the meeting of Council the reply received from the Treasury, which states that—

"My Lords, while fully agreeing with you, that the question of the administration of these collections is one of the utmost importance as regards the future progress of natural history in this country, are also of opinion that there is nothing which, on a point requiring so much con-

sideration, calls for instant decision. They think that the reasons which led them in 1877 to constitute the present Meteorological Council, rather than to create a new Government department, are not without weight in regard to displacing the trustees of the British Museum. My Lords do not intend to propose to Parliament any immediate change in the management of these collections, and they would be glad to find that the reasons which had led to the recommendations of the Royal Commission had been found to be capable of being met without any serious departure from the principles of a more or less indepenent trust."

It was generally agreed that this reply was very disappointing, and after remarks from various Members of Council, Prof. Huxley drew attention to the paragraph in the Treasury's letter where the manner in which the meteorological body had been dealt with, was mentioned, and said that to make any such comparison would be simply ludicrous. The Meteorological Committee was composed of the greatest experts in meteorology within the three kingdoms. He desired to speak with every respect of such distinguished persons as the trustees of the British Museum, but he could not say that they stood in the same position to natural history. There was no point of resemblance in referring to the placing of meteorology in the hands of a meteorological council. If the Treasury was prepared to place the management of the natural history department of the British Museum in the hands of a body which corresponded in zoology to what meteorology was in the meteorological council, that was an exceedingly intelligent proposition, and the General Committee should consider it carefully before they said anything against it, for it came very much to what the committee was advocating. As the Treasury appeared to be still fluid and mobile, it might be well that the General Committee replied to the letter, saying that the Treasury themselves suggested a basis on which they could construct an administration which would be perfectly satisfactory to the British Association, and therefore it would be perfectly agreeable to all round.

The sum received for tickets this year has been 1,425*l*.

Next year the Association meets at Swansea, when Prof. Ramsay will be President. In 1881 the Association celebrates its jubilee at York—a year behind time.

The following grants have been made :—

	£
A—Mathematics and Physics	
Lodge, Dr.—New Form of High Insulation Key	10
Adams, Prof.—Standard of White Light	20
Everett, Prof.—Underground Temperature	10
Joule, Dr.—Determination of the Mechanical Equivalent of Heat	50
Thomson, Sir W.—Elasticity of wire	50
Glaisher, Mr.—Luminous Meteors	30
Darwin, Mr. G. H.—Lunar Disturbance of Gravity ...	30
Sylvester, Prof.—Fundamental Invariants	50
Perry, Mr. J.—Laws of Water Friction	20
Ayrton, Mr. W. E.—Specific Inductive Capacity of Sprengel Vacuum	20
Haughton, Rev. Prof.—Completion of Tables of Sun-heat Co-efficients	50
Forbes, Prof. G.—Instrument for Detection of Fire-damp in Mines	10
Thomson, Mr. J. M.—Inductive Capacity of Crystals and Paraffines	25
B—Chemistry

SECTION A

MATHEMATICAL AND PHYSICAL

Opening Address by G. Johnstone Stoney, M.A., F.R.S., Secretary to the Queen's University in Ireland

In order that we may understand the present position of natural science upon the earth, we must remember that the universe is in itself one great whole, which includes minds no less than bodies, for thought is as much a phenomenon of what really exists as motion. But though the universe be but one, man with his limited powers is unable to treat it as such, but has to push his investigation of nature when and where he can. Thus have arisen many sciences which were at first quite isolated. Their separate condition is a mark of the feebleness of our powers of investigation. Their gradual convergence, and especially where any complete contact can be established between them, is the mark that our advancing knowledge is penetrating deeper.

That there are many sciences of nature, instead of one science of nature, has its relation, then, to human imperfection. But the coalescence of sciences has commenced, and is steadily taking place ; magnetism is no longer isolated from electricity, nor light from heat, nor the power of thinking from the condition of the brain. In all such cases we have got nearer to understanding what is really going on in natnre. There are already many such achievements of science, but nevertheless it remains true that human powers of investigation are so narrow, and the use we have made of them up to the present is so short of what we may reasonably look for in the future, that the sciences of nature are still many, and most of them stand lamentably aloof from one another.

We find, then, in the present passing condition of our knowledge, one group of sciences which investigate the phenomena of consciousness, another distinct group of the biological sciences, and a third, the group of the physical sciences. These are all but parts of the one great investigation of nature, but for the present they exist almost disconnected, as separate provinces of human inquiry.

After remarking on the complication of the Biological Sciences Prof. Stoney said :—

In the rest of the study of nature we are not embarrassed by the phenomena of life, and many mysteries therefore stand aside out of our path. Here lies the domain of the physical sciences. It is here that the mind of man has best been able to cope with the realities of the Universe, and in which its greatest achievements have been effected. It is here that exact reasoning finds a predominant place.

The process of investigation in the exact sciences is fundamentally one in all cases. It has been well described by Mill in the Third Book of his Logic. Nevertheless it is notorious that minds which are well fitted for some branches of physical inquiry, find difficulty—sometimes insuperable difficulty—in pursuing others. It is not every eminent mathematician who would have made an equally good chemist, or *vice versâ*. This is because there exists a practical distinction separating the investigations of exact science into two well-marked classes when they are viewed, not as they are in themselves, but in their relation to the powers of us, human beings. I refer to the distinction between the experimental method or the method of observation, on the one hand, and the deductive method or the method of reasoning, on the other. All valid investigations in exact science appeal to what can be directly perceived, and all lead to a conclusion which can be reasoned out from it ; but there are some of these investigations in which the main difficulty consists in

making the appeal to the senses, and there are others in which the main difficulty lies in the process of reasoning.

To contend with these difficulties successfully requires very different qualities of mind and body. In experimental science the powers principally called into requisition are readiness and closeness of observation, dexterity in manipulation, skill in devising expedients, accuracy in making adjustments, and great patience. It also requires that the investigator should have an accurate memory of what else he has witnessed resembling the phenomenon under observation, that he should be quick to detect every point of agreement and difference that can be perceived, and be skilful to select those which are significant and to employ them as materials for prevision to guide his further proceedings. But the strain on the reasoning powers is generally less, often of trifling amount. The question is put to Nature, and it is Nature usually that gives the bulk of the answer. The most striking monument of splendid achievements by the experimental method of investigation unaided by the deductive method is to be found in the science of chemistry.

An equally typical instance of the power of the deductive method is the science of mechanics. This science, which has sunk deeper into the secrets of Nature than any other science, and which is the science towards which all other physical sciences are at present more or less gravitating, is essentially deductive. There is little or no difficulty about its fundamental data. They are facts of Nature, so patent to all men, and so indelibly implanted in human conception, that some persons have supposed that we have an intuitive perception of them. But, while the materials from which the mind is to work are thus easily obtained, it has taxed to the utmost the reasoning powers of understandings like Newton's to evolve the few consequences of them which are already known, and the investigator has to call to his assistance every aid to prolonged consecutive thought which mathematicians can devise.

In grappling with the problems of Nature we are seldom allowed the choice of the method of investigation we shall employ. This is commonly settled for us and not by us. Where we cannot advance without further information, we must make further observations, *i.e.*, we must employ the experimental method, the appeal *ad experientiam;* where we cannot advance without understanding better what the information we possess really amounts to, we must employ the deductive method. . . .

After referring to Kirchhoff's investigations as an example Prof. Stoney said:—Wherever data are known exactly, there inferences from these data, however remote, may be depended upon as corresponding with what actually occurs in nature. And if, in such cases, the mind of man has proved equal to the task of drawing inferences which can effectually grapple with the problems he finds around him in the universe—which is, alas, as yet but too seldom—then will the deductive method, our plummet, explore depths in the great ocean of existence which our anchors of experiment could not have reached.

The distinction which is here made between deductive and experimental investigations would have no place in a logical system. But it has direct reference to human convenience, and derives its importance from this circumstance. It is obvious, too, that an investigation may partake of both characters—that it may require all the powers of the scientific observer to get at the facts, or even to appreciate them, and all the resources of the mathematician to elicit the consequences of them. For instance, on beginning his electrical studies the student of nature must master a mixed experimental and deductive inquiry to get at the elementary fact that free electricity resides either at or outside the surfaces of conductors; and he must engage in a further inquiry, and one only within the reach of a trained mind, to deduce from this the law of the inverse square. And, again, no full appreciation or even intelligent use of the common electrostatic and electrodynamic measures, which he meets at the threshold of his electrical studies, is within the reach of the mere experimentalist or of the mere theorist. And if this treacherous ground lies before the immature student at his entrance, what shall we say of the bogs he struggles into as he advances? We are perpetually meeting with inquiries of this mixed character in electricity and some of the other physical sciences, but they are comparatively rare in either mechanics or chemistry, and none that is difficult lies in the path of the beginner. How many students are there who are made to slur over the above and a multitude of similar difficulties, and who are told that they are learning science, when in fact what they are really learning is the pernicious habit of being content to see nature through a fog or through other men's mental eyes.

In mechanics valuable progress can be made by the mere mathematician, the student of deductive science; and in chemistry similar progress can be made by the mere experimentalist. Of all the physical sciences these are the most purely deductive and the most purely experimental. What I desire particularly to invite attention to is that the two great methods of investigation may best be acquired in these two sciences, and that for a really sound grasp of the remaining physical sciences, and especially with a view to further advance in physical science, a command of both methods of investigation is essential. But then, to bestow this invaluable power on the scientific student, the great science of mechanics must be presented to him in its own true form, and not degraded by the vile art of avoiding the legitimate use of the infinitesimal calculus in order to comply with the ill-judged conditions of some examination; and our practical chemistry must be made something more scientific than instruction in the lucrative art of the analyst.

We must bear in mind, too, that either method of investigation may be misapplied, and that this is a risk carefully to be guarded against. The deductive method, when misapplied, lands us in speculation, the experimental method becomes empiricism; and it so happens that the sciences of mechanics and chemistry are not only monuments of the power of the two great methods of investigation, but instructive examples of their weakness also. For in chemistry scarce any attempt at prolonged reasoning, carrying us by any lengthened flight to a distance from the experiments, can be relied on. The result has seldom risen to anything better than speculation. And on the other hand, in mechanics conclusions which depend on experiments only are empirical; that is, they are deficient in accuracy and their relation to the other phenomena of the science is left in darkness. Here, then, we find in these two sciences not only how strong these two methods of investigation are, but how weak they may become if misapplied. . . .

I have sought to show that it is in the study of mechanics and the practice of chemistry that the two great methods of investigation may best be acquired. In them they may be studied separately, by steps of graduated difficulty, and with a superabundance of materials; and each of them supplies the necessary cautions with respect to the method which is all-powerful in the other. No scientific man is really equipped for the pursuits in which both methods have to be employed till he has separately acquired a grasp of each. For it is only then that he will be armed against the errors which lead so many to mistake empiricism on the one hand and speculation on the other for solid science, or to underrate solid science, mistaking it for speculation. Nor is it only in his scientific occupations that he will derive benefit from this training. All exact reasoning, whether in science or in common life, belongs to these great divisions; and in the numberless instances in which we must be satisfied with reasoning which falls short of being exact, our only safety lies in having by the practice of exact reasoning, both deductive and experimental, attained to that intellectual tact and caution which alone will enable us to handle with safety the sharp and slippery tool. It is thus I am persuaded that a sound judgment with regard to truth may best be acquired by man or woman; and soundness of judgment is the noblest endowment of man's understanding, just as veracity is first among his virtues.

SECTION D

BIOLOGY

Department of Anatomy and Physiology

ADDRESS BY P. H. PYE-SMITH, B.A., M.D., VICE-PRESIDENT OF THE SECTION

THE Association to which we belong seeks to advance Natural Science, that is, accurate knowledge of the material world, by the following means:—

First.—By bringing together men who are engaged in the various fields of science indicated by our several sections, by promoting friendship between them, by giving opportunity for discussion on points of difference, by encouraging obscure but genuine labourers with the applause of the leaders whom they have learnt to venerate, and by fostering that feeling of respect for other branches of science, that knowledge of and interest in their progress, which chiefly marks the liberality of scientific study.

Secondly.—The Association provides funds, which, though

small in amount, are great in worth, from the mode of their distribution; and serve in a limited degree as an encouragement, though not an endowment, of research. One proof of the value of this method of subsidising unremunerative work by small grants distributed by the master workmen themselves is given by the fact that the sum of 4,000*l.* annually contributed by the Government of the United Kingdom for the endowment of research is distributed on the same plan by a Committee of the Royal Society.

The Third most important aim of our Association is, "to obtain a more general attention to the objects and methods of science, and the removal of any disadvantages of a public kind which impede its progress." It is for this reason that the Association travels from one to another of the great centres of population and intellectual activity of the kingdom. Local scientific societies and local museums are generated and regenerated in its path, local industries are for a time raised to a higher level than that of money-getting, and every artisan may learn how his own craft depends upon knowledge of the facts of nature, and how he forms part of the great system of applied science which is subduing the earth and all its powers to the use of man. We wish to make science popular, not by deceiving idlers into the belief that any thorough knowledge can be easy, but by exciting interest in its objects and appreciation of its methods. In the popular evening lectures you will hear those who are best qualified to speak upon their several subjects, not preaching with the dry austerity of a pedant, but bringing their own enthusiasm to kindle a contagious fire in those who hear them.

Endeavouring to aid in these objects, I shall in this introductory address offer you some considerations upon the bearing of biology in general, and anatomy and physiology in particular, upon national well-being and public interests.

Biology is the science of the structure, the functions, the distribution, and the succession in time of all living beings. If the proper study of mankind be man, he has learnt late in the inquiry that he can only understand himself by recognising that he is but one in the vast network of organic creation; that intelligible human anatomy must be based upon comparative anatomy; that human physiology can only be approached as a branch of general physiology, and that even the humblest mould or seaweed may furnish help to explain the most important problems of human existence.

The branch of physiology which is concerned with man, not as an individual, but a family, the branch which we now call Anthropology, is obviously related to practical politics, and it was not without reason that the late illustrious pathologist Rokitansky began a speech in the Upper House of the Austrian Parliament on the autonomy of the Bohemian nation with the words, "The question really is whether the doctrine of Darwin be true or no."

In another department, that of psychology, the physiology of the nervous system has already thrown more light upon the mysterious phenomena of consciousness than was gained by the acutest minds of all ages without the help of anatomical methods.

All the improvements of modern agriculture and stock-breeding rest upon more or less fully understood scientific principles, and the more perfectly the results have been first worked out in the laboratory the more safe and the more lucrative will be their application in the field.[1]

Still more important is the relation of physiology to the national health. The commonplaces of hygiene which are now, one may be thankful to say, taught, if not practised, in almost every schoolroom and factory in England, are the direct results of the abstruse researches of Boyle and Priestley, of Lavoisier and Pasteur. Ages of experience did not teach mankind the value of fresh air, or the innocence of clean water. Indeed, I have myself heard astonishment expressed by a German professor at the peculiar immunity with which English skins will bear the daily and unstinted application of soap and water.

If the art of keeping a community in health is but the application of plain physiological laws, it is no less true that the art of restoring the health, curative as distinct from preventive medicine, rests upon the same basis. In former days the physician was one who recognised what he called the disease of his patient, who referred to his books of precedents as a lawyer to his statutes, and who prescribed a proper remedy to cast out the disease. We now know that disease is, as the name implies, a purely subjective conception. The disease of a host is the health of the parasite, and we cure a human sufferer by poisoning the animals or plants which interfere with his comfort. The same changes which in the old man are the natural steps of decay, the absence of which after a certain age would be truly pathological, are the cause of acute disease in the young. Pathology has no laws distinct from those of physiology.

When these now obvious considerations are thoroughly understood, it clearly follows that all "systems of medicine" are in their very nature condemned. All that the art of medicine can do is to apply a knowledge of natural laws, of mechanics, and of hydrostatics, of botany and zoology, of chemistry and electricity, of the behaviour of living cells and organs when subjected to the influence of heat and of cold, of acids and alkalies, of alcohols and ethers, of narcotics and stimulants, so as to modify certain deviations from ordinary structure and function which are productive of pain, or discomfort, or death. It is, therefore, plain that rational medicine, or keeping right and setting right the human body, must rest upon a knowledge of its structure and its actions, just as a steam-engine or a watch cannot be mended upon general principles, but only by one who is familiar with their construction and working, and who can detect the source of their irregularity.

An objector may say:—"Admitting that medicine is an art, it is a purely empirical art. You cannot detect the origin of many of the maladies which you are yet able to cure; your best remedies have not been obtained by scientific experiment, but by chance, observation, and accumulated experience; and if you doctors would give more time to practical therapeutics, that is, to finding out what is good for the several aches and pains we complain of, you would spend your time better than in abstruse researches into microscopic anatomy or the properties of a dead frog's muscle."

The answer to the objection is an appeal to fact. For centuries so called observation and experience left medicine in the condition it occupied at the end of the seventeenth century. The progress of therapeutics is to be marked, not by the labours of "practical men," (who, by the way, are of all the most theoretical, only that their theories are wrong), but by the, at first sight, unconnected studies of Descartes and Newton, of Hooke and Grew, of Lavoisier and Davy and Volta, of Marshall Hall and Johannes Müller.

The history of science proves that unconnected, unsystematic, inaccurate observations are worth nothing. For untold ages men have had ample opportunities of studying the indications of the weather, and have felt the utmost desire to obtain a knowledge of what they portend. Yet it may fairly be said that nothing had been done to the purpose, until combined and systematic observations were made in this country and America. The fact is, that popular notions do not rest upon experience or observation. They rest, with scarcely an exception, upon metaphysical theories. In dealing with uneducated persons, both of the lower and higher ranks, physicians find abundance of theories as to the nature and the origin of disease, and of suggestions as to its cure. The only thing which would be of value is what we can scarcely ever get, an accurate observation of what they see and feel. Every fallacy of popular medicine, every solemn medical imposture, is the ghost of some long defunct doctrine of the schools. Therefore it is that common experience is almost absolutely useless in practical arts. They, without exception, depend for their progress upon the advance of science, that is, upon methodical, continuous, and scrupulously accurate observations and experiments.

Many important advances in the practice of medicine have been gained by direct and intentional experiments instituted with a therapeutical object. Such was the Hunterian operation for aneurism, the process of skin-grafting, and subperiosteal operations; such was the administration of chloroform and the introduction of nitrite of amyl, chloral hydrate, and carbolic acid. Such direct experiments still go on, and among them deserve mention for the skill and the untiring patience with which they were carried out, those investigations upon the action of various drugs on the secretion of bile for which we are indebted to Prof. Rutherford and his coadjutors. Even apparently accidental discoveries were not made accidentally. Hundreds of country surgeons must have been familiar with the cow-pox, and have seen examples of the immunity it conferred from the more terrible variola, but he who discovered vaccination was no falsely called practical man. He was a man of science, the

[1] I need only refer to the fruitful labours of Mr. Lawes and Dr. Gilbert in this direction.

friend of Hunter and of Cavendish, an anatomist and natural philosopher. The fruits of Jenner's discovery are spread over the whole earth. This humble village doctor has saved more lives than the most glorious conqueror destroyed, but his name is little honoured, and the only monument to his memory has been banished from association with vulgar kings and skilful homicides to an obscure corner of the great city, where his only homage is the health and beauty of the children who play around his statue.

But after all, it is not so much by direct and immediate contributions to the art of healing that physiology has vindicated her ancient title of the institutes of medicine, numerous and important as these contributions have been. It is still more by the scientific spirit which has transformed the empty learning so justly ridiculed by Molière and Le Sage into the practical efficiency of modern surgery. Let me give an instance of what I mean. The notion of measuring the temperature of the body is simple enough, and the rough observation that in inflammation the temperature is raised had led to the various terms by which it was denoted in ancient medicine, and to numberless theories now happily forgotten. But although the thermometer was well known, and had been applied by many scientific physicians, notably by De Haen, by Dr. John Davy, and by Sir Benjamin Brodie, yet the practical value of the clinical thermometer which now every practitioner carries in his pocket was not understood until the other day. Those only who had been trained in accurate physical and physiological investigations, who had learned the worse than uselessness of "rough observation," were able to see the enormous importance of clinical thermometry. This most practical of modern improvements in medicine would never have been dreamt of by "practical men": we owe it to the scientific training of German laboratories.

If physiology is of such great national importance, if the necessity of experimental research is so vital to the common national wealth, to agriculture and commerce, to health and well-being, ought not its well-ascertained results to be taught in our common schools, and its prosecution directly encouraged by the State?

There is no question of the great importance of children being taught the rudimentary laws of health, the bodily evils of dirt and sloth and vice, the excellence of temperance, the danger of the first inroads of disease. Such teaching, now broadcast in many excellent manuals as "The Personal Care of Health," by the late Dr. Parkes, and Dr. Bridges' "Catechism of Health," is no doubt extremely valuable, and happily is daily more and more diffused. But when beyond the direct utility of such knowledge, we attempt to make it an intellectual discipline, there are, I conceive, difficulties which will always prevent even elementary physiology from forming an important part of general education. First, there is the practical difficulty of the necessary dissections, next the impossibility of making physiology demonstrative, and thirdly, the abstruseness of the subject. It is impossible to have even an elementary knowledge of the laws of living beings without a very considerable familiarity with those of physics and of chemistry, and even in medical schools it requires all our efforts to prevent it degenerating into a mere dogmatic statement of results, or a laboured repetition of hearsay statements. As an intellectual discipline, for facility of demonstration, for the simplicity of the objects, their beauty and interest, their associations with the green lanes and broad moors of England, with the poetry of *Cymbeline* and *Lycidas*, with fairy tales and local folk-lore—Botany is to my mind the branch of natural science which is above all others to be chosen where one only can be taught. Next in importance I would place elementary physics, the knowledge of the simplest laws of masses at rest and in motion, of heat and light. Its great recommendations are its precision, its constant and useful illustrations in daily life, the interest it gives to the handicrafts and manufactures in which so large a number of English boys and girls are busied, and the necessity of such knowledge as the first step in acquiring all other natural sciences.

First, then, I would that every Sheffield girl should love flowers with the deep and abiding affection of familiar knowledge, and that every Sheffield lad should know every common plant in your beautiful woods and find his purest pleasure on the heights of Bell Hagg and the broad expanse of Stanage Moor. And next I would that your workmen and workboys should know so much of mechanics that they may take an intelligent pride in your vast factories, and that in some of them may be awakened the genius to which we trust to repeat in future generations the national services of Arkwright, and Watt, and Stevenson.

With regard to the endowment of research in biology, I must confess that I should be sorry to see it undertaken by government funds. That such investigations are of public interest, that they are difficult and expensive, and that at present they languish for want of adequate support, is all true. But this country is not so poor, nor our countrymen so wanting in public spirit, that we need appeal to the national purse to supply every ascertained want. Great as is the national importance of science, the nation is more important still; and even if that were the alternative, I would rather that we should indefinitely continue dependent on Germany for our knowledge than give up the local energy, the unofficial zeal which has made England what she is. Far better for the strength and the civilisation of the nation that a thousand pounds were raised every year for the endowment of unremunerative researches in this wealthy town of Sheffield than that ten thousand were paid you by a paternal monarch or an enlightened department.

But surely there is no need for us to go to Parliament for such sums as we require. In the first place, scientific men themselves show a good example of not asking before they give. There is the modest sum which we raise in this Association, there are the funds for helping research of the Royal Society, the Chemical Society, the British Medical Association, the Iron and Steel Institute, the Whitworth Scholarships. Next we have the resources of our Universities, which have scarcely begun to apply themselves to the task. I need do no more than allude to the Cavendish Laboratory, or to the Physiological School at Cambridge, where a simple college tutor, of rare ability, and of still more rare sympathy and energy, has in ten years, achieved results which we need not shrink from comparing with those of the great continental laboratories. The magnificent Museum of Anatomy, maintained by the College of Surgeons almost entirely out of their own funds, is another instance of private care for science to which we find no parallel abroad; and the Zoological Society wisely spends a large part of its income in prosecuting comparative anatomy, and in publishing its beautifully illustrated memoirs.

But besides the efforts of scientific bodies and the wealth of our national Universities, we may surely look to the public spirit of ancient companies and corporations to do something for the cause of science. In the middle ages our country was covered with parish churches by private munificence; in the sixteenth century most of our public and grammar schools were endowed; in later times our great religious and charitable societies were founded. May we not hope that, before the close of the present century, the discriminating knowledge which alone prevents gifts of money from being a curse instead of a blessing to a community, may lead to the establishment of libraries, and museums, and laboratories by universities and towns, which shall bear comparison, I will not say with those of Paris, or Leipsic, or Bonn, but with the poorer but scarcely less distinguished schools of Heidelberg and Göttingen, of Würzburg and of Utrecht?

Where we have institutions already under government control and patronage, let them be maintained as efficiently and liberally as possible. The British Museum, and its library, the Royal Observatory at Greenwich, and the Royal Gardens at Kew (happily preserved for the present from the short-sighted eagerness of those who would destroy their scientific value), these are great national institutions of which we are justly proud. Successive Governments will have enough to do to maintain their efficiency and to guard them from incompetent interference.

Whatever may be thought of the duty of the State directly to encourage the pursuit of animal and vegetable physiology, one would have supposed that at least what diplomatists call a benevolent neutrality, would be shown to a pursuit so labourious and costly, which demands trained workmen and the devotion of a lifetime, which is so important for the national wealth and health, and which, by reason, by experience, and by testimony, we know to be the only guarantee for advance in the various branches of the healing art. Why is it then that institutions which owe nothing to government assistance, and men who spend their time and talents in self-denying and unremunerative service for the public good, are not suffered to pursue their beneficent work in peace?

You know that certain persons who profess to be shocked by the methods of physiological research have succeeded in placing

this branch of science under as great disabilities as that sense of humour would allow, which so often redeems British ignorance from its most mischievous results.

The method that has given rise to so much excitement is the performance of experiments upon living animals. Now, if this were injurious to the greatest good of the greatest number of the community, or if freedom to perform these experiments interfered with the freedom of other persons to abstain from them, or if such experiments were forbidden by any religious or moral authority, by the Ten Commandments, or by Mr. Matthew Arnold, of course they must be given up; but equally, of course, the science of physiology must also come to a stop, and the farmer, the cattle-breeder, and the physician must be content with such knowledge or such ignorance as he at present possesses. I know it has been asserted that the science of the functions of living organs is quite independent of experiment upon living organs. But this is said by the same persons who have denied that the art of setting right the functions of the body when they go wrong has anything to do with the knowledge of what those functions are.

If you could be persuaded that chemistry can make progress without retorts and balances, that a geologist's hammer is a useless incumbrance, or that engineers can build bridges just as well by the rule of thumb as by the knowledge gained in a workshop, then you might believe that physiology also is independent of experiment.

It is absurd to object to the difficulties of the research or even the contradictory results sometimes obtained. The functions of a muscle or a gland are more complicated than those of water or gas, and their investigation needs greater skill, more caution and more frequent repetition. Imperfect experiments can lead to nothing but error; criticism from other physiologists, or from scientific men experinced in other branches of research, is not wanting and is always welcome. But vague assertion that further progress is impossible by the very means which have led to all our present knowledge, coming from those who "who are not of our school"—or any school, is undeserving of serious notice.

The real contention of course is a moral one, that we ought to relinquish the advantage of all experiments which are accompanied with pain to the creature experimented on. The botanist may serve his plants as he pleases, and even the animal physiologist may cut, or starve, or poison all sentient organisms which happen not to possess a backbone, and he may try experiments with all backboned animals, including himself and his friends, so long as they do not hurt, but that must be the limit. On the most extreme humanitarian views no objection can be made to experiments upon animals in a state of insensibility to pain, and as these constitute, happily, the vast majority of physiological experiments, the question is narrowed to comparatively restricted limits. Is it wrong to inflict painful experiments upon animals for the sake of science? In the absence of any authority to appeal to, we can but judge of the matter by analogy. Now it has been the practice of all mankind, and is still allowed by the common consent both of law and feeling, that we should destroy by more or less painful means, that we should enslave and force to work, and mutilate by painful operations, and hunt to death, and wound, and lacerate, and torture the brute creation for the following objects:—for our own self-preservation, as when we offer a reward for the killing of tigers and snakes in India; for our comfort as when we poison or otherwise destroy internal parasites, and vermin, and rats, and rabbits. Our safety, our food, our convenience, our wealth, or our amusement: all these objects have been and are regarded by the great mass of mankind, and are held by the laws of every civilised country, to be sufficiently important to justify the infliction of pain or death upon animals in whatever numbers may be necessary. The only restriction which Christian morality or in certain cases recent legislation imposes upon such practises is, that no more pain shall be inflicted than is necessary for the object in view. Killing or hurting domestic animals when moved by passion or by the horrible delight which some depraved natures feel in the act of inflicting pain was until lately the only recognised transgression against the law of England. I trust I need not say that it is only under such restrictions that physiologists desire to work.[1] Any one who would inflict a single pang beyond what is necessary for a scientific object, or would by carelessness fail to take due care of the animals he has to deal with, would be justly amenable to public reprobation. And, remember it is within these limits that the whole controversy lies, for after a long and patient examination of all that could be said by our accusers, the Royal Commission which was nominated for the purpose unanimously reported that in this country at least scientific experiments upon animals are free from abuse.

What is deliberately asserted is that within the restrictions which all humane persons impose upon themselves, it is lawful to inflict pain or death upon animals for profit or for sport, for money or for pastime; that property and sport are in England sacred things; but that the practises which they justify are unjustifiable when pursued with the object of increasing human knowledge or of relieving human suffering.

Of those persons who answer that they consider vivisection for the sake of sport to be almost as detestable as vivisection for the sake of duty, I would only ask first that they should deal impartially with both offences, and secondly that since in the one case their opinions are opposed to the practice of genteel society, and in the other to the convictions of all who are qualified to judge, they should at least contemplate the possibility of being mistaken. Putting the question of field sports altogether aside, you know perfectly well that in every village in England an extremely painful mutilation is constantly performed upon domestic animals in no registered laboratory, under no anæsthetics, and with no object but the convenience and profit of the owner. You remember how when an epidemic threatened the destruction of valuable property, every booby peer now eager to stop, so far as in him lay, the advance of knowledge, was no less eager to have carried out at the public expense any slaughter and any experiments, painful or otherwise, which would save his pocket.

But you will say: all this seems reasonable enough; but if so, how do you account for the prejudice against you, what has induced so many amiable and otherwise sane persons to join in the outcry against physiology?

First, I answer, it is due to the most frequent cause of folly—Ignorance. Many persons supposed to be educated are so destitute of the most ordinary conceptions of natural science that they do not understand the necessity for experiments. So little do they appreciate the difference between formal knowledge and real knowledge, that a distinguished statesman once assured me that he would as soon have his leg set by a man who had gained what he called his knowledge from books, as by one who had "walked the hospitals." Next, there is the vulgar dislike of whatever is not obviously and immediately useful. When knowledge for its own sake is in question, those of the baser sort are always ready to cry with equal ignorance of literature and of science, "*cui bono?*"

In another class of persons, less ignorant and less stupid than these two, opposition to physiological experiments appears to spring from what may fairly be stigmatised as Sentiment, that is to say, excitable, rather than deep feeling, uncontrolled by reason. People first gratify their fancy by calling cats and dogs our fellow creatures, which, in one sense, undoubtedly they are, and then, by the familiar fallacy of an ambiguous middle term, argue that it is cruel to put our fellow creatures to pain; or, as some would add, to reduce them to slavery, or to use them in any way for our own, rather than their good. Such persons compel their fellow creatures to drag them through the streets, they eat their fellow creatures when sufficiently vivisected to be palatable, and then find philosophical excuses for those who kill their fellow creatures for fun. But they are properly shocked when their fellow creatures are hurt or killed for the benefit of mankind. Such persons have been accused of feminine weakness; but I must say that I have never found an intelligent woman who could not see the rights of the case when fairly explained to her, whereas I have met a few men who on this, as in other matters, consistently refuse to give up to argument the notions which were formed by prejudice.

This sentiment is, I admit, the degradation of just feeling. To many unaffectedly compassionate hearts there is a peculiar pang in thinking of suffering which is deliberately inflicted, with only the justification of duty, instead of the excuse of ignorance or passion. They see in the helplessness of the dumb animals an appeal for pity, almost like that of childhood, and are justly indignant with the selfish cruelty so often exercised upon them. All honour to the efforts which have banished so many cruel sports from England; all honour to the Society which seeks to prevent cruelty to animals. If it can

[1] They are, in fact, the very limits that were put on record by this Association long before the agitation against physiology began. See Report for 1871, p. 144.

point to any additional means by which the sufferings of animals in the cause of science can be diminished, we shall be anxious to adopt them. If it can point to any abuse in one of our laboratories, we will hasten to correct it. This society has honourably declared that they know of none. That physiologists have been heedless, or even callous, in their experiments upon animals in past times, when men were strangely insensible even to human suffering, or in countries where a healthy result of Christian civilisation has not yet been seen in habitual gentleness to animals, I need not deny. Such cases have been eagerly sought and sometimes most unfairly judged. Only lately a learned body felt itself not strong enough to retain the admittedly invaluable services of an eminent foreigner, who had once admitted that when absorbed in scientific and beneficent researches he lost sight of any pain that might be inflicted.[1] Is not this the very excuse which is held valid in the case of sport? Doubtless we ought to be ever mindful of every branch of duty, but such occasional forgetfulness does not show hardness of heart. It is an excusable weakness for a student of medicine to shudder or to faint at the sight of blood, but he learns that this merely physical sensibility becomes selfish and mischievous if indulged: he is taught to suppress all such exhibition of emotion, and to let it stimulate without paralysing his efforts to relieve. But no one surely would think the hysterical youth more truly humane than the surgeon whose compassion is shown in the very firmness with which he inflicts a temporary pain for an ultimate good.

I have hitherto rested the whole argument upon the lawfulness of inflicting pain and death upon the lower animals for the sake of science and humanity, but as a matter of fact I may again assure those who, while assenting to the justice of the plea, yet shrink from what it may involve, that the great majority of experiments upon animals are rendered painless, and that the remainder are mostly those experiments which are most immediately and directly subservient to medical art, and happily even these are generally productive rather of discomfort than of pain. Let me give you an example of such a vivisection, far more painful than the immense majority of those of the laboratory. Suppose a country surgeon were sent for late at night to some case of urgent peril; knowing that his ride is for life or death, and unsparing of himself or his horse, he rides him to the utmost limits of endurance, and beyond: who would not applaud the action? Those only who appear deliberately to believe that our life is worth less than that of many sparrows, those legislators only who look forward to the time when wars will cease, not because of human slaughter, of devastated homes, of all the horrors which the world has endured for centuries, but because of the cruelties to which the horses in the artillery are subjected. We, who are familiar with human suffering and sorrow, which our knowledge is all too feeble to prevent, best understand how in testing some new remedy on a less precious fellow creature than a man, one who is truly humane may be tempted to forget the comparatively trivial suffering of a rabbit or a frog.

But some enthusiastic opponent will say, "I cannot pretend to doubt that these experiments are in every sense of the word useful, but we ought not to purchase the benefit they confer by inflicting pain upon innocent creatures. I would sign a petition to-morrow to put down all field sports by law, I would allow no operation upon domestic animals, and I will abstain from all animal food until I am certain that I can eat creatures which have been killed without suffering pain. But if I were lying at the point of death, and you brought an animal to my bedside and assured me that by putting it to pain my life would be saved, I would refuse to purchase it on such cruel terms." We may hope that the excellent person who made this heroic profession would in the hour of trial be better advised, but if not we may surely reply, "Right reverend sir, you are the best judge of the value of your own life, and if you think proper to sacrifice it to the comfort of a guinea-pig we must submit to the loss with such resignation as we can muster; but when you say that in obedience to this silly whim you will let your dearest friend suffer, allow the sacrifice of the most important life, and forbid those studies which have already rescued multitudes from deformity and misery and death, then those of us who have to do with the real responsibilities of life, and on whom presses the awful sense of impotence to which our defective science too often leaves us, answer that we too have duties to fulfil, and to the best of our power we mean conscientiously to fulfil them.

There is, I fear, another reason which animates much of the opposition to physiological experiments. It is nothing else than aversion from the methods and the results of science. It may be that an excuse for this dislike has been furnished by the pretence of false science, and the arrogance of much even which is true. But surely, no reasonable creature, from such trivial irritation, can deliberately wish to check the progress of accurate knowledge by observation and experiment. There are, indeed, some who, fearing (as I think prudently) that, "while a little philosophy inclineth men to atheism, depth in philosophy bringeth men's mind's about to religion," and desiring to subject the human mind to a bondage as hard and more degrading than that of mediæval Rome, would gladly call off interest from the unremunerative labours which are prompted only by the thirst for knowledge and faith in the possibility of learning more and more of the divine order of the world, to pursuits which bring obvious and material utility. There are those again, who, fearing (as I think foolishly) that increasing knowledge of this divine order will lower our admiration of its beauty, or that the better a man understands the laws of God the more likely he is to break them, have an unfeigned dislike for natural science in general, and for biology in particular. They repeat over again the error of which the Dominican friars, with far greater excuse, were guilty when they imprisoned Galileo. If any such are here, may I venture to tell them—in quietness and in confidence is your strength: the vast fabric of Christian morals is in no danger of being overturned by the discovery of a new chemical method in the laboratory, or of a hitherto undescribed animalcule. If noisy attacks are made in the injured name of science, you have only to wait, and you will see these attacks repelled by the true leaders of science themselves, or, at the worst, by the next generation. But if, leaving your secure fortress of defence, you come down with your rhetoric and your sentiments, your *petitio principii*, your *ignoratio elenchi*, and all your familiar fallacies and tropes, thinking that with such weapons you can meet, on their own ground, men who have spent their lives in the study of science, then no wonder if you suffer grievous defeat. Happy for you if you learn, like another discomfited pilgrim, to betake yourselves to another "weapon."

But I imagine that some of my audience are saying: "This defence would have been necessary before the Royal Commission made their report; but when that was made, and affirmed the necessity of physiological experiments, and the groundlessness of accusations of cruelty against physiologists, when an act was passed which licenses physiological laboratories, under the very restrictions which you had already imposed upon yourselves, may we not regard the controversy as closed, and the result as satisfactory?"

I answer that I have taken up your time with this defence of physiological experiments partly because I would fain help, however feebly, in the enlightenment of the public conscience, but also because the result of recent legislation is *not* satisfactory.

Science does not work readily in fetters. A system of licences and certificates, numerous and complicated, obtained with trouble and delay, and revocable at the will of a Minister who may, by the accidents of party, be at any time amenable to anti-scientific influences, such a system adds serious difficulties to those already in the way of experiments.

Suppose, as an illustration, that certain persons opposed on various grounds to learning, and especially hostile to Greek, had attacked the study of Plato. They would point out the danger of modern ladies becoming as well read in his writings as was Lady Jane Grey. They would show that the laxity of modern manners was coincident with the popularity of the "Symposium" and that the notorious increase of infanticide was the result of the teaching of the "Republic." Associations for the total suppression of Plato would be formed, with hired advocates, and anonymous letters, and "leaflets," spreading a knowledge of his most objectionable passages. Scholars would be threatened with eternal punishment, and schoolmasters with the withdrawal of their pupils. Then a royal commission would be appointed—a great Latin scholar, a Whig and a Tory statesman (who, having taken a B.Sc. degree at Oxford would be impartially ignorant of Greek) the

[1] Fortunately, Dr. Klein, whose researches in microscopic anatomy and pathology are so well known and appreciated, knows that he retains the confidence and respect of his scientific brethren, and we hope that his honourable connection with the largest school of medicine in London, will strengthen other and closer ties in binding him to England.

most intelligent despiser of Plato who could be found, the master of a grammar school on the modern side, and (perhaps the most efficient of all) a lawyer, who knew nothing about Greek but hated cant. This commission would take evidence that the Platonic writings were not all immoral, that they had been quoted with approval by Fathers of the Church, that they were of great importance to literature and philosophy, and even to the elucidation of the Sacred Writings. It would also be proved that the Platonic Dialogues were far less immoral than multitudes of other widely circulated books, or than a French novel which one of the royal commissioners happened to be reading, and, lastly, that the morals of Greek scholars, and of clergymen who had read Plato at college, were not obviously degraded below those of other people. On the other hand, witnesess would depose that a knowledge of Plato was of no consequence to a student of philosophy; that if it were, the text was in so corrupt a condition that no two scholars agreed as to a single chapter, and that, after all, philosophy was of no practical use, least of all to clergymen. Others would affirm that though they had never read a line of him, they knew that his style was as vicious as his sentiments; and perhaps some cross-grained scholar might be found who, having once edited a play of Euripides, would declare that all studies in Greek literature ought to be restricted to the tragedians, and that for his part he had never opened any other authors and had never felt the want of them.

At last the commission would report that there was no question of the value of the works of Plato, that it would be mischievous and impracticable to prohibit their study, and that there was no evidence that schoolmasters habitually chose the least edifying passages as lessons for boys. Then what is called a compromise would be made. It would be enacted that Plato might be read, but only in colleges annually licensed for that purpose; that every one wishing to read must have a general certificate signed by certain professors, and setting forth his object, also to be renewed every year; and that special certificates might be severally obtained for reading certain excepted dialogues, for copying from them, for publishing them, or, in rare cases, for translating them.

However reasonably such a system might be administered, who can doubt the result would be a diminution of the number of scholars, and a check to the progress of learning?

Now this is what legislation has done for physiological experiments. The Act [39 and 40 Victoria] was hastily drawn and hurriedly discussed; for noble lords and honourable gentlemen who had been taught from childhood to vivisect for unscientific purposes were eager to hurry off to their own merry vivisections, for which they were ready provided with licence and certificates. And it works as might be expected. Some shrink from seeing their names figure in disreputable newspapers, and receiving more or less savagely abusive anonymous letters. Others have no laboratories, and find difficulty in licensing their houses. Others are refused the certificates they require.

In one case two thoroughly qualified men were anxious to carry out an important investigation on the treatment of snake-bites. They procured venomous snakes from a distance, and applied for the special certificates necessary. Considerable delay ensued; various objections were raised, and set at rest; and at last all the certificates were obtained; but meantime the snakes had died.

I must apologise for having detained you so long. The whole history of this controversy is melancholy but instructive.

To those of my audience who wish well to science, I hope that I may have made more clear the grounds on which vivisection is necessary and right, and thus fulfilled one of the chief objects of the Association—"to obtain the removal of any disadvantage of a public kind which impedes the progress of science."

To those working physiologists who have honoured me by their presence I would express the assurance that they have the confidence and the gratitude of the medical profession, witnesses at once competent and impartial, who know the difficulties and the value of such labours; and as to present discouragements, looking back to the obstacles which so long retarded the progress of our kindred science, anatomy, I may say

O passi graviora, dabit Deus his quoque finem.

When, in the earliest years of the Royal Society, Sir Christopher Wren and Dr. Lower made those experiments on transfusion of blood which have at last proved so beneficent, there were not wanting shallow witlings who scoffed at their researches. It was of them that Cowley wrote with a just indignation—

> Whoever would deposed Truth advance
> Into the throne usurped from it,
> Must feel at first the blows of ignorance
> And the sharp points of envious wit.

You have at least escaped the latter penalty.

> Dishonour fall on those
> Who would to laughter or to scorn expose
> So virtuous and so noble a design,
> So human for its use, for knowledge so divine!

You wish your calumniators no greater dishonour than failure to do mischief. You wish for yourselves no other reward than "the wages of going on."

Department of Anthropology

ADDRESS BY EDWARD B. TYLOR, D.C.L., F.R.S.

IN surveying modern scientific opinion, the student is often reminded of a doctrine proclaimed in the ancient hymns of the Zend-Avesta, that of *Zrvâna akarana*, or "endless time." Our modern schemes of astronomy, geology, biology, are all framed on the assumption of past time immense in length. In fact, one reason why the latter sciences grew so slowly till almost our own day, was their being shackled by the bonds of a short chronology, allowing no room for the long successive periods through which it is now clear that the earth with its plants and animals passed into their present state. Even the Science of Man, though concerned with the later forms of being, belonging to times which geologists treat as almost modern, has nevertheless to deal with periods of time extending far back beyond the range of history and chronology.

Looking back 4,000 to 5,000 years, what is the appearance of mankind as disclosed to us by the Egyptian monuments and inscriptions? Several of the best-marked races of man were already in existence, including the brown Egyptian himself, the dark-white Semitic man of Assyria or Palestine, the Central African of two varieties, which travellers still find as distinct as ever, namely, the black or Negro proper, and the copper-coloured negroid, like the Bongo or Nyam-nyam of our own time. Indeed, the evidence accessible as to ancient races of man goes to prove that the causes which brought about their differences in types of skull, hair, skin, and constitution, did their chief work in times before history began. Since then the races which had become adapted to their geographical regions may have, on the whole, undergone little change while remaining there, but some alterations are traced as due to migration into new climates. Even these are difficult to follow, masked as they are by the more striking changes produced by intermarriage of races. Now the view that the races of man are to be accounted for as varied descendants of one original stock is zoologically probable from the close resemblance of all men in body and mind, and the freedom with which races intercross. If it was so, then the fact of the different races already existing early in the historical period compels the naturalist to look to a prehistoric period for their development to have taken place in. And considering how strongly differenced are the Negro and the Syrian, and how slowly such changes of complexion and feature take place within historical experience, this prehistoric period was probably of vast length. The evidence from the languages of the world points in the same direction. In times of ancient history we already meet with families of languages, such as the Aryan and the Semitic, and as later history goes on many other families of language come into view, such as the Bantu or Kafir of Africa, the Dravidian of South India, the Malayo-Polynesian, the Algonquin of North America, and other families. But what we do not find is the parent language of any of these families, the original language which all the other members are dialects of, so that this parent tongue should stand towards the rest in the relation which Latin holds to its descendants, Italian and French. It is, however, possible to work back by the method of philological comparison, so as to sketch the outlines of that early Aryan tongue which must have existed to produce Sanskrit and Persian, Greek and Latin, German, Russian, and Welsh, or the outlines of that early Semitic tongue which must have existed to produce Assyrian, Phœnician, Hebrew, and Arabic. Though such theoretical reconstructions of parent language from their descendants may only show a vague and shadowy likeness to the

reality, they give some idea of it. And what concerns us here is that theoretical early Aryan and Semitic, or other such reconstructed languages, do not bring our minds appreciably nearer to really primitive forms of speech. However far we get back, the signs of development from still earlier stages are there. The roots have mostly settled into forms which no longer show the reasons why they were originally chosen, while the inflexions only in part preserve traces of their original senses, and the whole structure is such as only a long-lost past can account for. To illustrate this important point, let us remember the system of grammatical gender in Greek or German, how irrationally a classification by sex is applied to sexless objects and thoughts, while even the use of a neuter gender fails to set the confusion straight, and sometimes even twists it with a new perversity of its own. Many a German and Frenchman wishes he could follow the example of our English forefathers who, long ago, threw overboard the whole worthless cargo of grammatical gender. But looking at gender in the ancient grammars, it must be remembered that human custom is hardly ever wilfully absurd, its unreasonableness usually arising from loss or confusion of old sense. Thus it can hardly be doubted that the misused grammatical gender in Hebrew or Greek is the remains of an older and reasonable phenomenon of language; but if so, this must have belonged to a period earlier than we can assign to the theoretical parent language of either. Lastly, the development of civilisation requires a long period of prehistoric time. Experience and history show that civilisation grew up gradually, while every age preserves recognisable traces of the ages which went before. The woodman's axe of to-day still retains much of the form of its ancestor—the stone celt in its wooden handle; the mathematician's tables keep up in their decimal rotation a record of the early ages when man's ten fingers first taught him to count; the very letters with which I wrote these lines may be followed back to the figure of birds and beasts and other objects drawn by the ancient Egyptians, at first as mere picture-writing to denote the things represented. Yet, when we learn from the monuments what ancient Egyptian life was like towards 5,000 years ago, it appears that civilisation had already come on so far that there was an elaborate system of government, an educated literary priesthood, a nation skilled in agriculture, architecture, and metal work. These ancient Egyptians, far from being near the beginning of civilisation, had, as the late Baron Bunsen held, already reached its halfway house. This eminent Egyptologist's moderate estimate of man's age on the earth at about 20,000 years has the merit of having been made on historical grounds alone, independently of geological evidence, for the proofs of the existence of man in the quaternary or mammoth period had not yet gained acceptance.

My purpose in briefly stating here the evidence of man's antiquity derived from race, language, and culture, is to insist that these arguments stand on their own ground. It is true that the geological argument from the implements in the drift-gravels and bone-caves, by leading to a general belief that man is extremely ancient on the earth, has now made it easier to anthropologists to maintain a rationally satisfactory theory of the race-types and mental development of mankind. But we should by no means give up this vantage-ground, though the ladder we climbed by should break down. Even if it could be proved that the flint implements of Abbeville or Torquay were really not so ancient as the pyramids of Egypt, this would not prevent us from still assuming, for other and sufficient reasons, a period of human life on earth extending many thousand years farther back.

It is an advantage of this state of the evidence that it to some extent gets rid of the "sensational" element in the problem of fossil man, which it leaves as merely an interesting inquiry into the earliest known relics of savage tribes. Geological criticism has not yet absolutely settled either way the claims of the Abbé Bourgeois' flints from Thénay to be of miocene date, or of Mr. Skertchly's from Brandon to be glacial. The accepted point is that the men who made the ordinary flint implements of the drift lived in the quaternary period characterised by the presence of the mammoth in our part of Europe. More than one geologist, however, has lately maintained that this quaternary period was not of extreme antiquity. The problem is at what distance from the present time the drift-gravels on the valley slopes can have been deposited by water action up to one hundred feet or so above the present flood-levels. It does not seem the prevailing view among geologists that rivers on the same small scale as those at present occupying mere ditches in the wide valley-floors could have left these deposits on the hill sides at a time when they had not yet scooped out the valleys to within fifty or a hundred feet of their present depth. Indeed, such means are insufficient out of all proportion to the results, as a mere look down from the hill-tops into such valleys is enough to show. Geologists connect the deposit of the high drift-gravels with the subsidence and elevation of the land, and the powerful action of ice and water at the close of the Glacial age; and the term "Pluvial period" is often used to characterise this time of heavy rainfall and huge rivers. It was then that the rude stone implements of palæolithic man were imbedded in the drift-gravels with the remains of the mammoth and fossil rhinoceros, and we have to ask what events have taken place in these regions since? The earth's surface has been altered to bring the land and water to their present levels, the huge animals became extinct, the country was inhabited by the tribes whose relics belong to the neolithic or polished-stone age, and afterwards the metal-using Keltic nations possessed the land, their arrival being fixed as previous to 400 B.C., the king of the Gauls then being called by the Romans by the name *Brennus*, which is simply the Keltic word for "king"—in modern Welsh *brenin*. To take in this succession of events geologists and archæologists generally hold that a long period is required. Yet there are some few who find room for them all in a comparatively short period. I will mention Principal Dawson, of Montreal, well known as a geologist in this Association, and who has shown his conviction of the soundness of his views by addressing them to the general public in a little volume entitled "The Story of the Earth and Man." Having examined the gravels of St. Acheul, on the Somme, where M. Boucher de Perthes found his celebrated drift implements, it appeared to Dr. Dawson that, taking into account the probabilities of a different level of the land, a wooded condition of the country and greater rainfall, and a glacial filling up of the Somme valley with clay and stones subsequently cut out by running water, the gravels could scarcely be older than the Abbeville peat, and the age of this peat he estimates as perhaps less than four thousand years. Within this period Dr. Dawson includes a comparatively rapid subsidence of the land, with a partial re-elevation, which left large areas of the lower grounds beneath the sea. This he describes as the geological deluge which separates the post-glacial period from the modern, and the earlier from the later prehistoric period of the archæologists.

My reason for going here into these computations of Dr. Dawson's is that the date about 2,200 B.C., to which he thus assigns these great geological convulsions, is actually within historic times. In Egypt successive dynasties had been reigning for ages, and the pyramids had long been built; while in Babylonia the old Chaldæan kings had been raising the temples whose ruins still remain. That is to say, we are asked to receive, as matter of geology, that stupendous geological changes were going on not far from the Mediterranean, including a final plunge of I know not how much of the earth's surface beneath the waters, and yet national life on the banks of the Nile and the Euphrates went on unbroken and apparently undisturbed through it all. To us in this section it is instructive to see how the free use of paroxysms and cataclysms makes it possible to shorten up geological time. Accustomed as we are to geology demanding periods of time which often seem to history exorbitant, the tables are now turned, and we are presented with the unusual spectacle of chronology protesting against geology for encroaching on the historical period.

In connection with the question of quaternary man, it is worth while to notice that the use of the terms "primæval" or "primitive" man, with reference to the savages of the mammoth period, seems sometimes to lead to unsound inferences. There appears no particular reason to think that the relics from the drift-beds or bone-caves represent man as he first appeared on the earth. The contents of the caves especially bear witness to a state of savage art, in some respects fairly high, and which may possibly have somewhat fallen off from an ancestral state in a more favourable climate. Indeed, the savage condition generally, though rude and more or less representing early stages of culture, never looks absolutely primitive, just as no savage language ever has the appearance of being a primitive language. What the appearance and state of our really primæval ancestors may have been seems too speculative a question, until there shall be more signs of agreement between the anthropologists, who work back by comparison of actual races of man toward a hypothetical common stock, and the zoologists, who approach the problem through the species adjoining the human. There is, however, a point relating to the problem to which attention is

due. Naturalists not unreasonably claim to find the geographical centre of man in the tropical regions of the Old World inhabited by his nearest zoological allies, the anthropomorphous apes, and there is at any rate force enough in such a view to make careful quest of human remains worth while in those districts, from Africa across to the Eastern Archipelago. Under the care of Mr. John Evans a fund has been raised for excavations in the caves of Borneo by Mr. Everett, and though the search has as yet had no striking result, money is well spent in carrying on such investigations in likely equatorial forest regions. It would be a pity that for want of enterprise a chance, however slight, should be missed of settling a question so vital to anthropology.

While the problem of primitive man thus remains obscure, a somewhat more distinct opinion may be formed on the problem of primitive civilised man. When it is asked what races of mankind first attained to civilisation, it may be answered that the earliest nations known to have had the art of writing, the great mark of civilisation as distinguished from barbarism, were the Egyptians and Babylonians, who in the remotest ages of history appear as nations advanced to the civilised stage in arts and social organisation. The question is, under what races to class them? What the ancient Egyptians were like is well known from the monuments, which show how closely much of the present fellah population, as little changed in features as in climate and life, represent their ancestors of the times of the Pharaohs. Their reddish-brown skin, and features tending toward the negroid, have led Hartmann, the latest anthropologist who has carefully studied them, to adopt the classification of them as belonging to the African rather than the Asiatic peoples, and especially to insist on their connection with the Berber type, a view which seems to have been held by Blumenbach. The contrast of the brown Egyptians with the dark-white Syro-Arabians on their frontiers is strongly marked, and the portraits on the monuments show how distinctly the Egyptian knew himself to be of different race from the Semite. Yet there was mixture between the two races, and what is most remarkable, there is a deep-seated Semitic element in the Egyptian language, only to be accounted for by some extremely ancient and intimate connection. On the whole, the Egyptians may be a mixed race, mainly of African origin, perhaps from the southern Somaliland, whence the Egyptian tradition was that the gods came, while their African type may have since been modified by Asiatic admixture. Next, as to the early relations of Babylonia and Media, a different problem presents itself. The languages of these nations, the so-called Akkadian and the early Medic, were certainly not of the same family with either the Assyrian or the Persian which afterwards prevailed in their districts. Their connection with the Tatar or Turanian family of languages, asserted twenty years ago by Oppert, has since been further maintained by Lenormant and Sayce, and seems, if not conclusively settled, at any rate to have much evidence for it, not depending merely on similarity of words, such as the term for "god," Akkadian *dingira*, being like the Tatar *tengri*, but also on the similarity of pronouns and grammatical structure by postpositions. Now language, though not a conclusive argument as to race, always proves more or less as to connection. The comparison of the Akkadian language to that of the Tatar family is at any rate *primâ facie* evidence that the nations who founded the ancient civilisation of Babylonia, who invented the cuneiform writing, and who carried on the astronomical observations which made the name of Chaldæan famous for all time, may have been not dark-white peoples like the Assyrians who came after them, but perhaps belonged to the yellow race of Central Asia, of whom the Chinese are the branch now most distinguished in civilisation. M. Lenormant has tried to identify among the Assyrian bas-reliefs certain figures of men whose round skulls, high cheek-bones, and low-bridged noses present a Mongoloid type contrasting with that of the Assyrians. We cannot, I think, take this as proved, but at any rate in these figures the features are not those of the aquiline Semitic type. The bronze statuette of the Chaldæan king called Gudea, which I have examined with Mr. Pinches at the British Museum, is also, with its straight nose and long thin beard, as un-Assyrian as may be. The anthropological point towards which all this tends is one of great interest. We of the white race are so used to the position of leaders in civilisation, that it does not come easy to us to think we may not have been its original founders. Yet the white race, whether the dark-whites, such as Phœnicians or Hebrews, Greeks or Romans, or the fair-whites, such as Scandinavians and Teutons, appear in history as followers and disciples of the Egyptians and Babylonians who taught the world writing, mathemathics, philosophy. These Egyptians and Babylonians, so far as present evidence reaches, seem rather to have belonged to the races of brown and yellow skin than to the white race.

It may be objected that this reasoning is in several places imperfect, but it is the use of a departmental address not only to lay down proved doctrines, but to state problems tentatively as they lie open to further inquiry. This will justify my calling attention to a line of argument which, uncertain as it at present is, may perhaps lead to an interesting result. So ancient was civilisation among both Egyptians and Chaldæans, that the contest as to their priority in such matters as magical science was going on hotly in the classic ages of Greece and Rome. Looking at the literature and science, the arts and politics, of Memphis and of Ur of the Chaldees, both raised to such height of culture near 5,000 years ago, we ask, were these civilisations not connected, did not one borrow from the other? There is at present a clue which, though it may lead to nothing, is still worth trial. The hint of it lies in a remark by Dr. Birch as to one of the earliest of Egyptian monuments, the pyramid of Kochome, near Sakkara, actually dating from the first dynasty, no doubt beyond 3000 B.C., and which is built in steps like the seven-storeyed Babylonian temples. Two other Egyptian pyramids, those of Abu-sīr, are also built in steps. Now whether there is any connection between the building of these pyramids and the Babylonian towers, does not depend on their being built in stages, but in the number of these stages being seven. As to the Babylonian towers, there is no doubt, for though Birs-Nimrud is now a ruinous heap, the classical descriptions of such temples, and the cuneiform inscriptions, put it beyond question that they had seven stages, dedicated to the seven planets. As to the Egyptian pyramids, the archæologists Segato and Masi positively state of one step-pyramid of Abur-sir, that it had seven decreasing stages, while, on the other hand, Vyse's reconstruction of the step-pyramid of Sakkara shows there only six. Considering the ruinous state of all three step-pyramids, it will require careful measurement to settle whether they originally had seven stages or not. If they had, the correspondence cannot be set down to accident, but must be taken to prove a connection between Chaldæa and Egypt as to the worship of the seven planets, which will be among the most ancient links connecting the civilisations of the world. I hope by thus calling attention to the question, to induce some competent architect visiting Egypt to place the matter beyond doubt, one way or the other.

While speaking of the high antiquity of civilisation in Egypt, the fact calls for remark, that the use of iron as well as bronze in that country seems to go back as far as historical record reaches. Brugsch writes in his "Egypt under the Pharaohs," that Egypt throws scorn on the archæologists' assumed successive periods of stone, bronze, and iron. The eminent historian neglects, however, to mention facts which give a different complexion to the early Egyptian use of metals, namely, that chipped flints, apparently belonging to a prehistoric Stone Age, are picked up plentifully in Egypt, while the sharp stones or stone knives used by the embalmers seem also to indicate an earlier time when these were the cutting instruments in ordinary use. Thus there are signs that the Metal Age in Egypt, as elsewhere in the world, was preceded by a Stone Age, and if so, the high antiquity of the use of metal only throws back to a still higher antiquity the use of stone. The ancient iron-working in Egypt is, however, the chief of a group of facts which are now affecting the opinions of anthropologists on the question whether the Bronze Age everywhere preceded the Iron Age. In regions where, as in Africa, iron ore occurs in such a state that it can after mere heating in the fire be forged into implements, the invention of iron-working would be more readily made than that of the composite metal bronze, which perhaps indicates a previous use of copper, afterwards improved on by an alloy of tin. Prof. Rolleston, in a recent address on the Iron, Bronze, and Stone Ages, insists with reason that soft iron may have been first in the hands of many tribes, and may have been superseded by bronze as a preferable material for tools and weapons. We moderns, used to fine and cheap steel, hardly do justice to the excellence of bronze, or gun-metal as we should now call it, in comparison with any material but steel. I well remember my own surprise at seeing in the Naples Museum that the surgeons of Herculaneum and Pompeii used instruments of bronze. It is when hard steel comes in, that weapons both of bronze and wrought iron have to yield, as when the long soft iron broad-

swords of the Gauls bent at the first blow against the pikes of Flaminius' soldiers. On the whole, Prof. Virchow's remarks in the *Transactions* of the Berlin Anthropological Society for 1876, on the question whether it may be desirable to recognise instead of three only two ages, a Stone Age and a Metal Age, seem to put the matter on a fair footing. Iron may have been known as early as bronze or even earlier, but nevertheless there have been periods in the life of nations when bronze, not iron, has been the metal in use. Thus there is nothing to interfere with the facts resting on archæological evidence, that in such districts as Scandinavia or Switzerland a Stone Age was at some ancient time followed by a Bronze Age, and this again by an Iron Age. We may notice that the latter change is what has happened in America within a few centuries, where the Mexicans and Peruvians, found by the Spaniards living in the Bronze Age, were moved on into the Iron Age. But the question is whether we are to accept as a general principle in history the doctrine expounded in the poem of Lucretius, that men first used boughs and stones, that then the use of bronze became known, and lastly iron was discovered. As the evidence stands now, the priority of the Stone Age to the Metal Age is more firmly established than ever, but the origin of both bronze and iron is lost in antiquity, and we have no certain proof which came first.

Passing to another topic of our science, it is satisfactory to see with what activity the comparative study of laws and customs, to which Sir Henry Maine gave a new starting-point in England, is now pursued. The remarkable inquiry into the very foundations of society in the structure of the family, set afoot by Bachofen in his "Mütterrecht," and M'Lennan in his "Primitive Marriage," is now bringing in every year new material. Mr. L. H. Morgan, who, as an adopted Iroquois, became long ago familiar with the marriage laws and ideas of kinship of uncultured races, so unlike those of the civilised world, has lately made, in his "Ancient Society," a bold attempt to solve the whole difficult problem of the development of social life. I will not attempt here any criticism of the views of these and other writers on a problem where the last word has certainly not been said. My object in touching the subject is to mention the curious evidence that can still be given by rude races as to their former social ties, in traditions which will be forgotten in another generation of civilised life, but may still be traced by missionaries and others who know what to seek for. Thus, such inquiry in Polynesia discloses remarkable traces of a prevalent marriage-tie which was at once polygamous and polyandrous, as where a family of brothers were married jointly to a family of sisters; and I have just noticed in a recent volume on "Native Tribes of South Australia," a mention of a similar state of things occurring there. As to the general study of customs, the work done for years past by such anthropologists as Prof. Bastian, of Berlin, is producing substantial progress. Among recent works I will mention Dr. Karl Andree's "Ethnologische Parallelen" and Mr. J. A. Farrer's "Primitive Manners." In the comparison of customs and inventions, however, the main difficulty still remains to be overcome, how to decide certainly whether they have sprung up independently alike in different lands through likeness in the human mind, or whether they have travelled from a common source. To show how difficult this often is, I may mention the latest case I have happened to meet with. The Orang Dongo, a mountain people in the Malay region, have a custom of inheritance that when a man dies the relatives each take a share of the property, and the deceased inherits one share for himself, which is burnt or buried for his ghost's use, or eaten at the funeral feast. This may strike many of my hearers as quaint enough and unlikely to recur elsewhere; but Mr. Charles Elton, who has special knowledge of our ancient legal customs, has pointed out to me that it was actually old Kentish law, thus laid down in Law-French:—"Ensement seient les chateus de gauylekendeys parties en treis apres le exequies e les dettes rendues si il y est issne mulier en vye, issi que la mort eyt la une partie, e les fitz e les filles muliers lautre partie e la femme la tierce partie."—"In like sort let the chattels of gavelkind persons be divided into three after the funeral and payment of debts, if there be lawful issue living, so that the deceased have one part, and the lawful sons and daughters the other part, and the wife the third part." The Church had indeed taken possession, for pious uses, of the dead man's share of his own property; but there is good Scandinavian evidence that the original custom before Christian times was for it to be put in his burial-mound. Thus the right of the rude Malay tribe corresponds with that of ancient Europe, and the question which the evidence does not yet enable us to answer, is whether the custom was twice invented, or whether it spread east and west from a common source, perhaps in the Aryan district of Asia.

It remains for me to notice the present state of Comparative Mythology, a most interesting, but also most provoking part of Anthropology. More than twenty years ago a famous essay, by Prof. Max Müller, made widely known in England how far the myths in the classical dictionary and the story-books of our own lands might find their explanation in poetic nature-metaphors of sun and sky, cloud and storm, such as are preserved in the ancient Aryan hymns of the Veda. Of course it had been always known that the old gods and heroes were in some part personifications of nature—that Helios and Okeanos, though they walked and talked and begat sons and daughters were only the Sun and Sea in poetic guise. But the identifications of the new school went farther. The myth of Endymion became the simple nature-story of the setting Sun meeting Selene the Moon; and I well remember how, at the Royal Institution, the aged scholar, Bishop Thirlwall, grasped the stick he leant on, as if to make sure of the ground under his feet, when he heard it propounded that Erinys, the dread avenger of murder, was a personification of the Dawn discovering the deeds of darkness. Though the study of mythology has grown apace in these later years, and many of its explanations will stand the test of future criticism, I am bound to say that mythologists, always an erratic race, have of late been making wilder work than ever with both myth and real history, finding mythic suns and skies in the kings and heroes of old tradition, with dawns for love-tales, storms for wars, and sunsets for deaths, often with as much real cogency as if some mythologist a thousand years hence should explain the tragic story of Mary Queen of Scots as a nature-myth of a beauteous Dawn rising in splendour, prisoned in a dark cloud-island, and done to death in blood-red sunset. Learned treatises have of late, by such rash guessings, shaken public confidence in the more sober reasonings on which comparative mythology is founded, so that it is well to insist that there are cases where the derivation of myths from poetic metaphors is really proved beyond doubt. Such an instance is the Hindu legend of King Bali, whose austerities have alarmed the gods themselves, when Vâmana, a Brahmanic Tom Thumb, begs of him as much land as he can measure in three steps; but when the boon is granted, the tiny dwarf expands gigantic into Vishnu himself, and striding with one step across the earth, with another across the air, and a third across the sky, drives the king down into the infernal regions, where he still reigns. There are various versions of the story, of which one may be read in Southey; but in the ancient Vedic hymns its origin may be found when it was not as yet a story at all, only a poetic metaphor of Vishnu, the Sun, whose often-mentioned act is his crossing the airy regions in his three strides. "Vishnu traversed (the earth), thrice he put down his foot; it was crushed under his dusty step. Three steps hence made Vishnu, unharmed preserver, upholding sacred things." Both in the savage and civilised world there are many myths which may be plainly traced to such poetic fancies before they have yet stiffened into circumstantial tales; and it is in following out these, rather than in recklessly guessing myth-origins for every tradition, that the sound work of the mythologist lies. The scholar must not treat such nature-poetry like prose, spoiling its light texture with too heavy a grasp. In the volume published by our new Folk-Lore Society, which has begun its work so well, Mr. Lang gives an instance of the sportive nature-metaphor which still lingers among popular story-tellers. It is Breton, and belongs to that wide-spread tale of which one version is naturalised in England as "Dick Whittington and his Cat." The story runs thus:—The elder brother has the cat, while the next brother, who has a cock left him, fortunately finds his way to a land where (there being no cocks) the king has every night to send chariots and horses to bring the dawn; so that here the fortunate owner of Chanticleer has brought him to a good market. Thus we see that the Breton peasant of our day has not even yet lost the mythic sense with which his remote Aryan ancestors could behold the chariots and horses of the dawn. But myth, though largely based on such half-playful metaphor, runs through all the intermediate stages which separate poetic fancy from crude philosophy embodied in stories seriously devised as explanations of real facts. No doubt many legends of the ancient world, though not really history, are myths which have arisen by reasoning on actual events, as definite as that which, some four years ago, was terrifying the peasant mind in North

Germany, and especially in Posen. The report had spread far and wide that all Catholic children with black hair and blue eyes were to be sent out of the country, some said to Russia, while others declared that it was the King of Prussia who had been playing cards with the Sultan of Turkey, and had staked and lost 40,000 fair-haired blue-eyed children; and there were Moors travelling about in covered carts to collect them; and the schoolmasters were helping, for they were to have five dollars for every child they handed over. For a time the popular excitement was quite serious; the parents kept the children away from school and hid them, and when they appeared in the streets of the market-town the little ones clung to them with terrified looks. Dr. Schwartze, the well-known mythologist, took the pains to trace the rumour to its sources. One thing was quite plain, that its prime cause was that grave and learned body, the Anthropological Society of Berlin, who, without a thought of the commotion they were stirring up, had, in order to class the population as to race, induced the authorities to have a census made throughout the local schools, to ascertain the colour of the children's skin, hair, and eyes. Had it been only the boys, to the Government inspection of whom for military conscription the German peasants are only too well accustomed, nothing would have been thought of it; but why should the officials want to know about the little girls' hair and eyes? The whole group of stories which suddenly sprang up were myths created to answer this question; and even the details which became embodied with them could all be traced to their sources, such as the memories of German princes selling regiments of their people to pay their debts, the late political negotiations between Germany and Russia, &c. The fact that a caravan of Moors had been travelling about as a show accounted for the covered carts with which they were to fetch the children; while the schoolmasters were naturally implicated, as having drawn up the census. One schoolmaster, who evidently knew his people, assured the terrified parents that it was only the children with blue hair and green eyes that were wanted—an explanation which sent them home quite comforted. After all, there is no reason why we should not come in time to a thorough understanding of mythology. The human mind is much what it used to be, and the principles of myth-making may still be learnt from the peasants of Europe.

When, within the memory of some here present, the Science of Man was just coming into notice, it seemed as though the study of races, customs, traditions, were a limited though interesting task, which might, after a few years, come so near the end of its materials as no longer to have much new to offer. Its real course has been far otherwise. Twenty years ago it was no difficult task to follow it step by step; but now even the yearly list of new anthropological literature is enough to form a pamphlet, and each capital of Europe has its anthropological society in full work. So far from any look of finality in anthropological investigations, each new line of argument but opens the way to others behind, while these lines tend as plainly as in the sciences of stricter weight and measure, toward the meeting-ground of all sciences in the unity of nature

SECTION G

MECHANICAL SCIENCE

OPENING ADDRESS BY J. ROBINSON, PRES. INST. MECH. ENG., PRESIDENT OF THE SECTION

On the Development of the Use of Steel during the Last Forty Years, considered in its Mechanical and Economic Aspects

MUCH has been written by poets and others of a succession of the Ages of the human race in comparing their degradation with the various kinds of metal, considered metaphorically—thus we have the golden age, the silver age, the age of brass, and the age of iron.

Our own time may very appropriately and literally be described as a branch of the latter age, and be named the age of steel.

In the metropolis of the steel manufacture it would seem fitting that the Mechanical Section of this great scientific association should direct its attention to this wonderful metal, the uses of which are daily becoming more numerous and important.

But it may be said, on the other hand, that as the use of this material is perpetually growing more common, so are discussions as to its manufacture, composition, and characteristics, becoming almost wearisome from their frequency.

Notwithstanding an appearance of truth in this objection to our occupying more time in referring to the subject, I would venture to entertain the hope that a treatment of the question in its mechanical and economic aspects may prove not uninteresting to this meeting.

At the time when railway extension was becoming general, about forty years ago, the use of steel in this country was confined mainly to tools for mechanical purposes, including files and other articles, springs for vehicles, weapons of various sorts, and implements for agricultural and domestic uses; and it is proposed to measure the scientific and mechanical energy brought to bear upon the manufacture and improvement of this metal by the increase in the number of purposes to which it is applied, and the diminished price at which it can be obtained, as compared with the price at the time of its introduction for constructive works. There are, however, several important exceptions to this method of appreciation to which reference will hereafter be made.

We will take, then, the simplest form in the preceding list, viz., *tool steel*, the price of which for ordinary purposes varied from 50*s*. to 56*s*. per cwt. at the period I have named; and we shall find that the development of the manufacture of steel in general has but little affected this particular material, which is still produced in much the same fashion, *i.e.*, by the use of carefully selected Swedish iron, carburised by exposure in ovens to the heat of burning charcoal, and then recast from crucibles and hammered down to the required size. The result of a somewhat stationary condition of manufacture has been the maintenance of prices, at the same, or about the same, level up to the present time.

A superior quality of tool steel has been produced by the adoption of a process invented by Mr. R. Mushet, in which titanium is introduced in the manufacture, and which dates back to the year 1838-39. This steel is of great endurance when applied to the working of steel and iron of considerable hardness, and its higher price of 140*s*. per cwt. is quite justified by the excellent results obtained from its use, and other steels of similar fine quality are produced by several manufacturers, who make specialties of them.

Some twenty-seven or twenty-eight years ago, Krupp, of Essen, gave an enormous impulse to the application of steel, by his method of producing much larger masses of crucible steel than had previously been possible. He at that time accomplished the casting of an ingot of "crucible" steel of 50 cwt., a weight then considered incredible, and this was followed up by the production of weldless cast steel tyres in 1852, which led to the very rapid development in the use of his steel for railway tyres, cranked axles for locomotive and other engines, straight axles and shafts, and parts of machines in general.

It is most interesting to consider the prices of such of these objects as have up to this time maintained similar forms, with the object of ascertaining by the selling price, the progress in the scientific and mechanical appliances used for the production of the materials just referred to.

At the time of their coming into use, about twenty-five years ago, the price of cast steel tyres was 120*s*. per cwt.; it is now from 18*s*. to 25*s*. per cwt. The price of forged steel cranked axles was, when first introduced, 15*l*. per cwt.; it is now from 65*s*. to 70*s*. per cwt.

The price of straight axles and shafts was from 40*s*. to 50*s*. per cwt.; it is now from 19*s*. 6*d*. to 23*s*. per cwt.

Now to what do we owe this enormous reduction of price and consequent more frequent and more economic application? The answer must be that, following the initiation of Krupp, our English engineers and men of science set themselves to work to discover and apply new processes for the production and manufacture of this most wonderful metal; and I venture to say that in the whole history of metallurgy, from the time of Tubal Cain downwards, there has been no such progress in invention and manufacture as has been realised by the aid of such men as Mushet, Krupp, Bessemer, Siemens, Whitworth, Martin, Vickers, Betl, Bauschinger, Styffe, and many others within the period comprised in this retrospect; and our national predilections will perhaps lead us to the opinion that our own country may fairly appropriate a large share of merit for the results achieved.

Another of the uses of steel to which attention may be given is that of the production of cannon of large size.

Efforts had been made by some of our enterprising workers in metal to produce large guns of solid wrought iron; but the

processes of heating and hammering were attended with so much difficulty that the attempt was given up. Here again Krupp stepped in, and succeeded, thirty-two years ago, in manufacturing cannon of cast steel, which unhappily have become ordinary commodities with those nationalities who could afford such expensive weapons. Since that time Krupp has produced about 2,000 guns, the heaviest being, when finished, 72 tons (16 inch).

Sir William Armstrong and Sir Joseph Whitworth soon came into the field with guns of their own invention. The former, by adopting the system of iron coils applied externally to a central cylinder; and the latter, by shrinking cylindrical hoops on to a central cylinder made of cast steel.

In the adaptation of the steel manufacture of the cast or crucible steel period to the production of every object demanded by the march of engineering and mechanical science, I need not mention the names of individuals and firms in this town who have shown themselves equal to the task; but I will venture to say that their success has been such as to raise the town of Sheffield to the very pinnacle of fame as producing steel of any, even the highest quality demanded in the markets of the world.

I must now turn to a name honoured everywhere for the benefits and renown he has brought to his country by his inventions and appliances, developed during the last twenty-four or twenty-five years, in the manufacture of a steel which can be cheaply produced and readily adapted to the requirements of the purchaser. I am sure the audience will in their minds anticipate the record of the name of Bessemer—a name which will be handed down to posterity in connection with the manufacture of steel as long as that manufacture exists.

Another name which will most deservedly figure in the history of the development of the steel manufacture is one, like that of Bessemer, which has been known not only in that development, but in connection with many other discoveries in physical science—I mean that of Siemens, who, like his compeer, has not only invented processes, but has personally carried them out into practical application. An expression let fall by the latter as President of the Iron and Steel Institute at its meeting last year in Paris, exhibits very strikingly the absence of any other feeling on the part of these two great men save that of the most friendly rivalry.

Speaking of a comparison between the results of steel manufactured by the Bessemer blowing process and the Siemens-Martin open-hearth process, Dr. Siemens said, "He did not see how the result could be the same. It might be better in the Bessemer process than in the open hearth for aught he knew, but it could not be the same;" and it seems to augur well for the advancement of science in our day that so little of a contrary spirit is exhibited in the discussions which ensue from time to time upon any improved process either chemical or mechanical, having for its object the production of a better material at a lower first cost. The name of Robert Mushet may very properly be introduced here as one of our early inventors of the improved processes for the manufacture of steel, and it is gratifying to find that other countries besides England have learnt to appreciate the results obtained by him during so many years of scientific and experimental research.

It is needless that I should do more in an assembly like that before me than refer, in the simplest terms, to the differences in the processes of manufacture connected with these names.

In that of Bessemer, pig-iron of a selected quality is charged into what is technically called a "converter," a large cast-iron vessel into which air can be blown at considerable velocity by suitable blowing machinery. This goes on until the iron is thoroughly oxidised, and the impurities contained in the metal are driven off. When this happens the blowing ceases, and a certain proportion of Spiegeleisen or of ferro-manganese is added to the charge so as to give the required amount of carbon. Blowing recommences, this time only to effect complete mixture of the materials, and then the casting of the ingots takes place of a quality corresponding to the metal selected for the mixtures. A mild steel—or, as it has been called, a pure iron—is the resultant, and it is capable of being worked, welded, and hammered very much as in the case of the purest wrought irons; but it possesses generally a much higher tensile resistance and a greater ductility.

In the Siemens-Martin, or open-hearth process, a similar charge of pig-iron of the desired quality—probably hæmatite pig—is put into the bed of a reverberatory furnace of the regenerative system, and the necessary oxidation is produced by adding to the molten mass iron ores, or oxides of iron in proportions ascertained by experience, after which re-carbonisation is obtained by the addition of ferro-manganese or Spiegeleisen as in the Bessemer process.

These processes have been the great factors in that reduction in the cost price, and therefore in the extension of the use of such objects as steel tyres, axles, shafts, rails, &c., to which I have already referred, and which is so striking an instance of the results which our men of science can accomplish by their physical and experimental researches into the means of supplying the wants of our work-a-day world.

I will now draw attention to another product of the steel manufacture which is of immense importance, and which could not have been obtained for ordinary purposes but for the facilities of manufacture arising out of the inventions I have just alluded to —I mean that of steel castings, *i.e.* castings obtained from the crucible, precisely in the form in which they are to be used in the construction of machinery, just as is the case in ordinary cast iron run from the cupola furnace. This production of castings for engineering purposes is gaining an enormous and rapid development; and when it is considered that in this metal we obtain castings of a strength at least three to four times that of the strongest iron castings, the importance of this experimental discovery can scarcely be over-rated.

Nor must I pass over the application of these processes to the production of boiler plates, bridge girder plates, and ship plates, in which, as a result of the greater tensile resistance of such plates (reaching for ordinary uses a figure of about twenty-eight to thirty-four tons to the square inch), the engineer is not only enabled to lighten his structure, but to expect from it greater durability—an expectation not diminished by its greater capability of resisting corrosion, especially where care is taken to exclude manganese from the mixture of the metals employed.

For specific purposes, and where price is not so much an element of consideration as great tensile or percussive resistance, a more costly mode of manufacture has been adopted by Sir Joseph Whitworth, whose attention was probably drawn to the necessity for obtaining such a metal, during the construction of cannon and torpedoes, but which has now been extended to objects of a very varied character. The method of manufacture, which has been in use upwards of ten years, is by casting ingots under very heavy hydraulic pressures, from very carefully selected materials, the result being the production of a metal of enormous tensile resistance, reaching, in some instances, the high figure of 100 tons per square inch, while at the same time the bubbles and air vesicles, which sometimes appear in metal produced in the ordinary methods, are entirely or almost entirely got rid of, and the consequent striations and imperfections of internal structure and external surface disappear.

It is hoped that ere long we shall be able to procure in this way cylindrical boiler plates rolled solid from the ingot, much after the fashion in which weldless steel tyres are now obtained, and that the weakening of these plates by the existing necessity for forming horizontal riveted joints may thus be avoided.

It is desirable before closing this, I fear, already somewhat long address, to call attention to the most recent development of the steel manufacture as exhibited in the processes of Messrs. Snellus, Gilchrist, and Thomas, by which iron containing a considerable proportion of, say, 1·44 per cent. of phosphorus, may, in the course of its manufacture into either Bessemer or Seimens-Martin steel, have this deleterious matter entirely removed, or reduced to an inconsiderable proportion.

The method of carrying out this operation was exceedingly well described at the recent meeting of the Iron and Steel Institute in London, and it was shown that where such irons were melted in vessels lined with a slag having twenty per cent. of silica and thirty per cent. of lime and magnesia, the phosphorus was gradually and effectually absorbed by this lining, and a steel of good quality, comparatively free from phosphorus and silica, was produced.

The result to the community will naturally be that, as henceforth a much more extended area of our iron fields both at home and abroad will become available for the production of steel, the use of that metal will be still further extended and its price reduced mainly by means of the methodical researches of our scientific metallurgists, and entirely independently of those accidental combinations which have in less scientific days led to the adoption of new and improved methods in the production of metals required by the progress of mechanical and economic science.

ON RADIANT MATTER[1]

TO throw light on the title of this lecture I must go back more than sixty years—to 1816. Faraday, then a mere student and ardent experimentalist, was twenty-four years old, and at this early period of his career he delivered a series of lectures on the general properties of matter, and one of them bore the remarkable title, "On Radiant Matter." The great philosopher's notes of this lecture are to be found in Dr. Bence Jones's "Life and Letters of Faraday," and I will here quote a passage in which he first employs the expression *Radiant Matter*:—

"If we conceive a change as far beyond vaporisation as that is above fluidity, and then take into account also the proportional increased extent of alteration as the changes rise, we shall perhaps, if we can form any conception at all, not fall far short of radiant matter; and as in the last conversion many qualities were lost, so here also many more would disappear."

Faraday was evidently engrossed with this far-reaching speculation, for three years later—in 1819—we find him bringing fresh evidence and argument to strengthen his startling hypothesis. His notes are now more extended, and they show that in the intervening three years he had thought much and deeply on this higher form of matter. He first points out that matter may be classed into four states—solid, liquid, gaseous, and radiant—these modifications depending upon differences in their several essential properties. He admits that the existence of radiant matter is as yet unproved, and then proceeds, in a series of ingenious analogical arguments, to show the probability of its existence.[2]

If, in the beginning of this century, we had asked, What is a gas? the answer then would have been that it is matter, expanded and rarefied to such an extent as to be impalpable, save when set in violent motion; invisible, incapable of assuming or of being reduced into any definite form like solids, or of forming drops like liquids; always ready to expand where no resistance is offered, and to contract on being subjected to pressure. Sixty years ago such were the chief attributes assigned to gases. Modern research, however, has greatly enlarged and modified our views on the constitution of these elastic fluids. Gases are now considered to be composed of an almost infinite number of small particles or molecules, which are constantly moving in every direction with velocities of all conceivable magnitudes. As these molecules are exceedingly numerous, it follows that no molecule can move far in any direction without coming in contact with some other molecule. But if we exhaust the air or gas contained in a closed vessel, the number of molecules becomes diminished, and the distance through which any one of them can move without coming in contact with another is increased, the length of the mean free path being inversely proportional to the number of molecules present. The further this process is carried the longer becomes the average distance a molecule can travel before entering into collision; or, in other words, the longer its mean free path the more the physical properties of the gas or air are modified. Thus, at a certain point, the phenomena of the radiometer become possible, and on pushing the rarefaction still further, *i.e.*, decreasing the number of molecules in a given space and lengthening their mean free path, the experimental results are obtainable to which I am now about to call your attention. So distinct are these phenomena from anything which occurs in air or gas at the ordinary tension, that we are led to assume that we are here brought face to face with matter in a fourth state or condition, a condition as far removed from the state of gas as a gas is from a liquid.

[1] A lecture delivered to the British Association for the Advancement of Science, at Sheffield, Friday, August 22, 1879, by William Crookes, F.R.S.

[2] "I may now notice a curious progression in physical properties accompanying changes of form, and which is perhaps sufficient to induce, in the inventive and sanguine philosopher, a considerable degree of belief in the association of the radiant form with the others in the set of changes I have mentioned.

"As we ascend from the solid to the fluid and gaseous states, physical properties diminish in number and variety, each state losing some of those which belonged to the preceding state. When solids are converted into fluids, all the varieties of hardness and softness are necessarily lost. Crystalline and other shapes are destroyed. Opacity and colour frequently give way to a colourless transparency, and a general mobility of particles is conferred.

"Passing onward to the gaseous state, still more of the evident characters of bodies are annihilated. The immense differences in their weight almost disappear; the remains of difference in colour that were left are lost. Transparency becomes universal, and they are all elastic. They now form but one set of substances, and the varieties of density, hardness, opacity, colour, elasticity, and form, which render the number of solids and fluids almost infinite, are now supplied by a few slight variations in weight, and some unimportant shades of colour.

"To those, therefore, who admit the radiant form of matter, no difficulty exists in the simplicity of the properties it possesses, but rather an argument in their favour. These persons show you a gradual resignation of properties in the matter we can appreciate as the matter ascends in the scale of forms, and they would be supnsed if that effect were to cease at the gaseous state. They point out the greater exertions which nature makes at each step of the change, and think that, consistently, it ought to be greatest in the passage from the gaseous to the radiant form."—*Life and Letters of Faraday*, vol. i. p. 308.

Mean Free Path. Radiant Matter

I have long believed that a well-known appearance observed in vacuum tubes is closely related to the phenomena of the mean free path of the molecules. When the negative pole is examined while the discharge from an induction-coil is passing through an exhausted tube, a dark space is seen to surround it. This dark space is found to increase and diminish as the vacuum is varied, in the same way that the mean free path of the molecules lengthens and contracts. As the one is perceived by the mind's eye to get greater, so the other is seen by the bodily eye to increase in size; and if the vacuum is insufficient to permit much play of the molecules before they enter into collision, the passage of electricity shows that the "dark space" has shrunk to small dimensions. We naturally infer that the dark space is the mean free path of the molecules of the residnal gas, an inference confirmed by experiment.

I will endeavour to render this "dark space" visible to all present. Here is a tube (Fig. 1) having a pole in the centre in

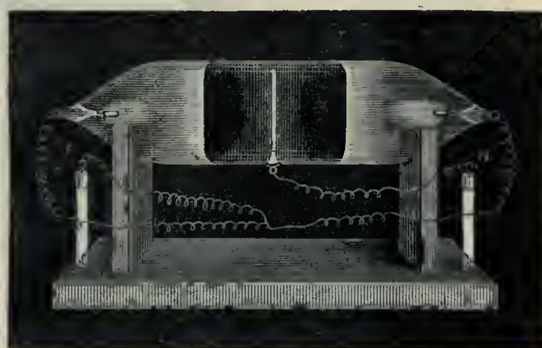

Fig. 1.

the form of a metal disk, and other poles at each end. The centre pole is made negative, and the two end poles connected together are made the positive terminal. The dark space will be in the centre. When the exhaustion is not very great the dark space extends only a little on each side of the negative pole in the centre. When the exhaustion is good, as in the tube before you, and I turn on the coil, the dark space is seen to extend for about an inch on each side of the pole.

Here, then, we see the induction spark actually illuminating the lines of molecular pressure caused by the excitement of the negative pole. The thickness of this dark space is the measure of the mean free path between successive collisions of the molecules of the residual gas. The extra velocity with which the negatively electrified molecules rebound from the excited pole, keeps back the more slowly moving molecules which are advancing towards that pole. A conflict occurs at the boundary of the dark space, where the luminous margin bears witness to the energy of the discharge.

Therefore the residual gas—or, as I prefer to call it, the gaseous residue—within the dark space, is in an entirely different state to that of the residual gas in vessels at a lower degree of exhaustion. To quote the words of our last year's President, in his address at Dublin:—

"In the exhausted column we have a vehicle for electricity not constant like an ordinary conductor, but itself modified by the passage of the discharge, and perhaps subject to laws differing materially from those which it obeys at atmospheric pressure."

In the vessels with the lower degree of exhaustion, the length of the mean free path of the molecules is exceedingly small as compared with the dimensions of the bulb, and the properties belonging to the ordinary gaseous state of matter, depending upon constant collisions, can be observed. But in the phenomena now about to be examined, so high is the exhaustion carried that the dark space around the negative pole has widened out till it entirely fills the tube. By great rarefaction the mean free path

has become so long that the hits in a given time in comparison to the misses may be disregarded, and the average molecule is now allowed to obey its own motions or laws without interference. The mean free path, in fact, is comparable to the dimensions of the vessel, and we have no longer to deal with a *continuous* portion of matter, as would be the case were the tubes less highly exhausted, but we must here contemplate the molecules *individually*. In these highly exhausted vessels the molecules of the gaseous residue are able to dart across the tube with comparatively few collisions, and radiating from the pole with enormous velocity, they assume properties so novel and so characteristic as to entirely justify the application of the term borrowed from Faraday, that of *Radiant Matter*.

Radiant Matter exerts powerful Phosphorogenic Action where it strikes

I have mentioned that the radiant matter within the dark space excites luminosity where its velocity is arrested by residual gas outside the dark space. But if no residual gas is left, the molecules will have their velocity arrested by the sides of the glass; and here we come to the first and one of the most noteworthy properties of radiant matter discharged from the negative pole—its power of exciting phosphorescence when it strikes against solid matter. The number of bodies which respond luminously to this molecular bombardment is very great, and the resulting colours are of every variety. Glass, for instance, is highly phosphorescent when exposed to a stream of radiant matter. Here (Fig. 2) are three bulbs composed of different glass: one is uranium glass (*a*), which phosphoresces of a dark green colour; another is English glass (*b*), which phosphoresces of a blue colour; and the third (*c*) is soft German glass—of which most of the apparatus before you is made—which phosphoresces of a bright apple-green.

My earlier experiments were almost entirely carried on by the aid of the phosphorescence which glass takes up when it is under the influence of the radiant discharge; but many other substances possess this phosphorescent power in a still higher degree than glass. For instance, here is some of the luminous sulphide of calcium prepared according to M. Ed. Becquerel's description. When the sulphide is exposed to light—even candle-light—it phosphoresces for hours with a bluish-white colour. It is, however, much more strongly phosphorescent to the molecular discharge in a good vacuum, as you will see when I pass the discharge through this tube.

Other substances besides English, German, and uranium glass, and Becquerel's luminous sulphides, are also phosphorescent.

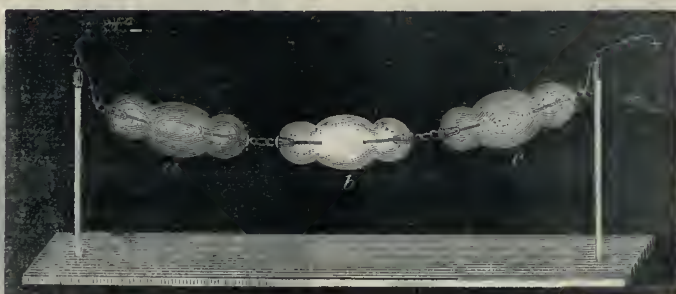

FIG. 2.

The rare mineral phenakite (aluminate of glucinum) phosphoresces blue; the mineral spodumene (a silicate of aluminium and lithium) phosphoresces a rich golden yellow; the emerald gives out a crimson light. But without exception, the diamond is the most sensitive substance I have yet met for ready and brilliant phosphorescence. Here is a very curious fluorescent diamond,

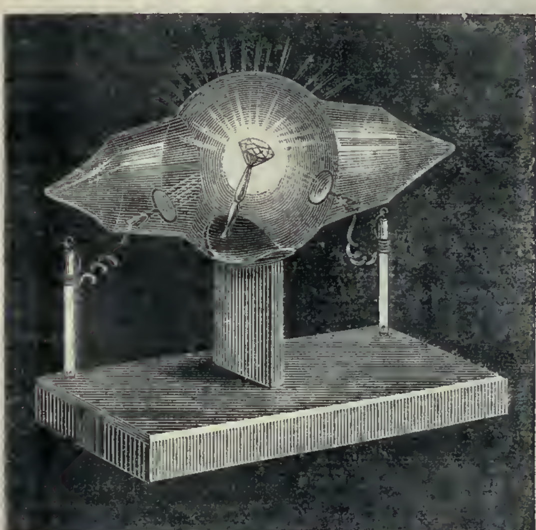

FIG. 3.

green by daylight, colourless by candle-light. It is monnted in the centre of an exhausted bulb (Fig. 3), and the molecular discharge will be directed on it from below upwards. On darkening the room you see the diamond shines with as much light as a candle, phosphorescing of a bright green.

Next to the diamond the ruby is one of the most remarkable stones for phosphorescing. In this tube (Fig. 4) is a fine collection of ruby pebbles. As soon as the induction-spark is turned on you will see these rubies shining with a brilliant rich red tone, as if they were glowing hot. It scarcely matters what colour the ruby is, to begin with. In this tube of natural rubies there are stones of all colours—the deep red and also the pale pink ruby. There are some so pale as to be almost colourless, and some of the highly-prized tint of pigeon's blood; but under the impact of radiant matter they all phosphoresce with about the same colour.

Now the ruby is nothing but crystallised alumina with a little

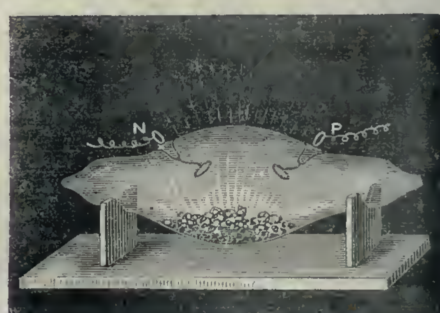

FIG. 4.

colouring-matter. In a paper by Ed. Becquerel,[1] published twenty years ago, he describes the appearance of alumina as glowing with a rich red colour in the phosphoroscope. Here is some precipitated alumina prepared in the most careful manner. It has been heated to whiteness, and you see it also glows under the molecular discharge with the same rich red colour.

The spectrum of the red light emitted by these varieties of alumina is the same as described by Becquerel twenty years ago. There is one intense red line, a little below the fixed line B in

[1] *Annales de Chimie et de Physique*, 3rd series, vol. lvii., p. 50, 1859.

the spectrum, having a wave-length of about 6895. There is a continuous spectrum beginning at about B, and a few fainter lines beyond it, but they are so faint in comparison with this red line that they may be neglected. This line is easily seen by examining with a small pocket spectroscope the light reflected from a good ruby.

There is one particular degree of exhaustion more favourable than any other for the development of the properties of radiant matter which are now under examination. Roughly speaking, it may be put at the millionth of an atmosphere.[1] At this degree of exhaustion the phosphorescence is very strong, and after that it begins to diminish until the spark refuses to pass.[2]

I have here a tube (Fig. 5) which will serve to illustrate the

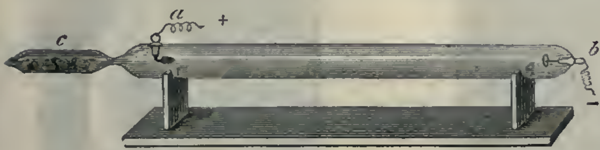

FIG. 5.

dependence of the phosphorescence of the glass on the degree of exhaustion. The two poles are at *a* and *b*, and at the end (*c*) is a small supplementary tube, connected with the other by a narrow aperture, and containing solid caustic potash. The tube has been exhausted to a very high point, and the potash heated so as to drive off moisture and injure the vacuum. Exhaustion has then been recommenced, and the alternate heating and exhaustion repeated until the tube has been brought to the state in which it now appears before you. When the induction-spark is first turned on nothing is visible—the vacuum is so high that the tube is non-conducting. I now warm the potash slightly, and liberate a trace of aqueous vapour. Instantly conduction commences, and the green phosphorescence flashes out along the length of the tube. I continue the heat, so as to drive off more gas from the potash. The green gets fainter, and now a wave of cloudy luminosity sweeps over the tube, and stratifications appear, which rapidly get narrower, until the spark passes along the tube in the form of a narrow purple line. I take the lamp away, and allow the potash to cool; as it cools, the aqueous vapour, which the heat had driven off, is re-absorbed. The purple line broadens out, and breaks up into fine stratifications; these get wider, and travel towards the potash tube. Now a wave of green light appears on the glass at the other end, sweeping on and driving the last pale stratification into the potash; and now the tube glows over its whole length with the green phosphorescence. I might keep it before you, and show the green growing fainter and the vacuum becoming non-conducting, but I should detain you too long, as time is required for the absorption of the last traces of vapour by the potash, and I must pass on to the next subject.

Radiant Matter proceeds in straight Lines

The radiant matter whose impact on the glass causes an evolution of light, absolutely refuses to turn a corner. Here is a V-shaped tube (Fig. 6), a pole being at each extremity. The pole at the right side (*a*) being negative, you see that the whole of the right arm is flooded with green light, but at the bottom it stops sharply and will not turn the corner to get into the left side. When I reverse the current and make the left pole negative, the green changes to the left side, always following the negative pole and leaving the positive side with scarcely any luminosity.

In the ordinary phenomena exhibited by vacuum tubes—phenomena with which we are all familiar—it is customary, in order to bring out the striking contrasts of colour, to bend the tubes into very elaborate designs. The luminosity caused by the phosphorescence of the residual gas follows all the convolutions into which skilful glass-blowers can manage to twist the glass. The

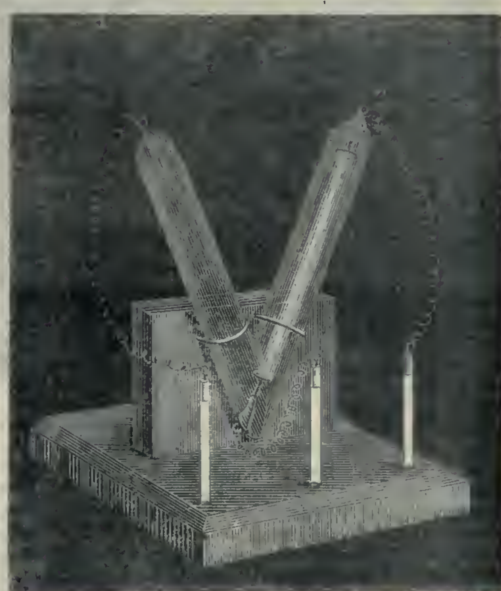

FIG. 6.

negative pole being at one end and the positive pole at the other, the luminous phenomena seem to depend more on the positive than on the negative at the ordinary exhaustion hitherto used to get the best phenomena of vacuum tubes. But at a very high exhaustion the phenomena noticed in ordinary vacuum tubes when the induction spark passes through them—an appearance of cloudy luminosity and of stratifications—disappear entirely. No cloud or fog whatever is seen in the body of the tube, and with such a vacuum as I am working with in these experiments, the only light observed is that from the phosphorescent surface of the glass. I have here two bulbs (Fig. 7), alike in shape and position of poles, the only difference being that one is at an exhaustion equal to a few millimetres of mercury—such a moderate exhaustion as will give the ordinary luminous phenomena—whilst the other is exhausted to about the millionth of an atmosphere. I will first connect the moderately exhausted bulb (A) with the induction-coil, and retaining the pole at one side (*a*) always negative, I will put the positive wire successively to the other poles with which the bulb is furnished. You see that as I change the position of the positive pole, the line of violet light joining the two poles changes, the electric current always choosing the shortest path between the two poles, and moving about the bulb as I alter the position of the wires.

This, then, is the kind of phenomenon we get in ordinary exhaustions. I will now try the same experiment with a bulb (B)

---

" " " "	=	1 atmosphere.

[2] Nearly 100 years ago Mr. Wm. Morgan communicated to the Royal Society a paper entitled "Electrical Experiments made to ascertain the Non-conducting Power of a Perfect Vacuum, &c." The following extracts from this paper, which was published in the *Phil. Trans.* for 1785 (vol. lxxv. p. 272), will be read with interest:—

"A mercurial gage about 15 inches long, carefully and accurately boiled till every particle of air was expelled from the inside, was coated with tin-foil 5 inches down from its sealed end, and being inverted into mercury through a perforation in the brass cap which covered the mouth of the cistern; the whole was cemented together, and the air was exhausted from the inside of the cistern through a valve in the brass cap, which, producing a perfect vacuum in the gage, formed an instrument peculiarly well adapted for experiments of this kind. Things being thus adjusted (a small wire having been previously fixed on the inside of the cistern to form a communication between the brass cap and the mercury, into which the gage was inverted) the coated end was applied to the conductor of an electrical machine, and notwithstanding every effort, neither the smallest ray of light, nor the slightest charge, could ever be procured in this exhausted gage."

"If the mercury in the gage be imperfectly boiled, the experiment will not succeed; but the colour of the electric light, which, in air rarefied by an exhauster, is always violet or purple, appears in this case of a beautiful green, and, what is very curious, the degree of the air's rarefaction may be nearly determined by this means; for I have known instances, during the course of these experiments, where a small particle of air, having found its way into the tube, the electric light became visible, and, as usual, of a green colour; but the charge being often repeated, the gage has at length cracked at its sealed end, and in consequence the external air, by being admitted into the inside, has gradually produced a change in the electric light from green to blue, from blue to indigo, and so on to violet and purple, till the medium has at length become so dense as no longer to be a conductor of electricity. I think there can be little doubt, from the above experiments, of the non-conducting power of a perfect vacuum."

"This seems to prove that there is a limit even in the rarefaction of air, which sets bounds to its conducting power; or, in other words, that the particles of air may be so far separated from each other as no longer to be able to transmit the electric fluid; and if they are brought within a certain distance of each other their conducting power begins, and continually increases till their approach also arrives at its limit."

that is very highly exhausted, and as before, will make the side pole (a') the negative, the top pole (b) being positive. Notice how widely different is the appearance from that shown by the last bulb. The negative pole is in the form of a shallow cup. The molecular rays from the cup cross in the centre of the bulb, and thence diverging fall on the opposite side and produce a circular patch of green phosphorescent light. As I turn the bulb round you will all be able to see the green patch on the glass. Now observe, I remove the positive wire from the top, and connect it with the side pole (c). The green patch from the divergent negative focus is there still. I now make the lowest pole (d) positive, and the green patch remains where it was at first, unchanged in position or intensity.

We have here another property of radiant matter. In the low vacuum the position of the positive pole is of every importance, whilst in a high vacuum the position of the positive pole scarcely matters at all; the phenomena seem to depend entirely on the negative pole. If the negative pole points in the direction of the positive, all very well, but if the negative pole is entirely in the opposite direction it is of little consequence: the radiant matter darts all the same in a straight line from the negative.

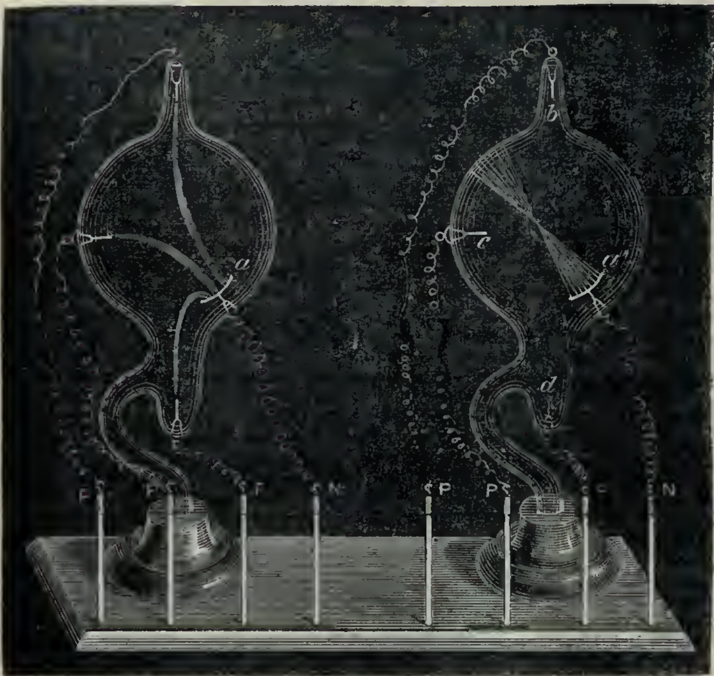

FIG. 7.

FIG. 8.

If, instead of a flat disk, a hemi-cylinder is used for the negative pole, the matter still radiates normal to its surface. The tube before you (Fig. 8) illustrates this property. It contains, as a negative pole, a hemi-cylinder (a) of polished aluminium. This is connected with a fine copper wire, b, ending at the platinum terminal, c. At the upper end of the tube is another terminal, d. The induction-coil is connected so that the hemi-cylinder is negative and the upper pole positive, and when exhausted to a sufficient extent the projection of the molecular rays to a focus is very beautifully shown. The rays of matter being driven from the hemi-cylinder in a direction normal to its surface, come to a focus and then diverge, tracing their path in brilliant green phosphorescence on the surface of the glass.

Instead of receiving the molecular rays on the glass, I will show you another tube in which the focus falls on a phosphorescent screen. See how brilliantly the lines of discharge shine out, and how intensely the focal point is illuminated, lighting up the table.

Radiant Matter when intercepted by Solid Matter casts a Shadow

Radiant matter comes from the pole in straight lines, and does not merely permeate all parts of the tube and fill it with light, as would be the case were the exhaustion less good. Where there is nothing in the way the rays strike the screen and produce phosphorescence, and where solid matter intervenes they are obstructed by it, and a shadow is thrown on the screen. In this pear-shaped bulb (Fig. 9) the negative pole (a) is at the pointed end. In the middle is a cross (b) cut out of sheet aluminium, so that the rays from the negative pole projected along the tube will be partly intercepted by the aluminium cross, and will project an image of it on the hemispherical end of the tube which is phosphorescent. I turn on the coil, and you will all see the black shadow of the cross on the luminous end of the bulb (c, d). Now, the radiant matter from the negative pole has been passing by the side of the aluminium cross to produce the shadow; the glass has been hammered and bombarded till it is appreciably warm, and at the same time another effect has been produced on the glass—its sensibility has been deadened. The glass has got tired, if I may use the expression, by the enforced phosphorescence. A change has been produced by this molecular bom-

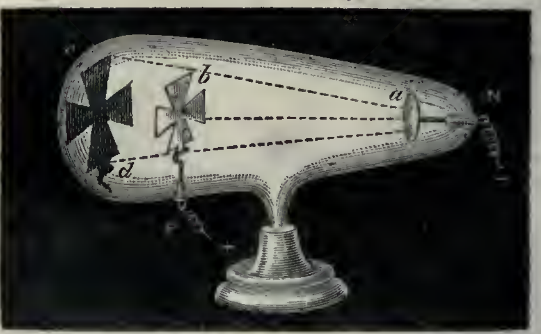

FIG. 9.

bardment which will prevent the glass from responding easily to additional excitement; but the part that the shadow has fallen on is not tired—it has not been phosphorescing at all and is perfectly fresh; therefore if I throw down this cross—I can easily do so by giving the apparatus a slight jerk, for it has been most ingeniously constructed with a hinge by Mr. Gimingham—and so allow the rays from the negative pole to fall uninterruptedly on to the end of the bulb, you will suddenly see the black cross

(*c*, *d*, Fig. 10) change to a luminous one (*e*, *f*), because the background is now only capable of faintly phosphorescing, whilst the part which had the black shadow on it retains its full phosphorescent power. The stencilled image of the luminous cross unfortunately soon dies out. After a period of rest the glass partly recovers its power of phosphorescing, but it is never so good as it was at first.

Here, therefore, is another important property of radiant matter. It is projected with great velocity from the negative pole, and not only strikes the glass in such a way as to cause it to vibrate and become temporarily luminous while the discharge is going on, but the molecules hammer away with sufficient energy to produce a permanent impression upon the glass.

(*To be continued.*)

NOTES

In accordance with the resolution come to at the recent International Congress of Meteorology, the International Committee have issued circulars for a special Conference at the Deutsche Seewarte at Hamburg, on October 1, to consider the scheme of Count Wilczek and Lieut. Weyprecht for the establishment of circumpolar observing stations. The Conference will consider specially the following points:—1. The number of observatories and the most convenient places at which to establish them. The decision will depend on the number of co-operating states and the sums which they are willing to devote to this purpose. Count Wilczek and Lieut. Weyprecht have proposed the following places:—In the Northern Hemisphere: north coasts of Spitzbergen and of Novaya Zemlya, the neighbourhood of the North Cape, the mouth of the Lena, New Siberia, Point Barrow, on the north-east of Behring Strait, west coast of Greenland, east coast of Greenland, about 75° N. lat. In the Southern Hemisphere: the neighbourhood of Cape Horn, Kerguelen or Macdonald Islands, one of the groups south of the Auckland Islands. 2. There will be considered the exact epoch of the observations and their maximum duration. 3. Uniform instruction for observations, which will have to fix especially: (*a*) The minimum of elements to be observed at each station, both for meteorological phenomena and for those of terrestrial magnetism, as well as for other phenomena of terrestrial physics connected with them. (*b*) The minimum number of daily observations for the different elements. (*c*) The first meridian which will serve as basis for simultaneous observations. (*d*) Methods of observation for the different elements and methods of reduction. (*e*) Instruments of observation and their arrangement, as far as they may influence the comparability of the results.

At a recent meeting of the Committee of the Iron and Steel Institute in Liverpool it was arranged that this year's meeting should be held in Liverpool on September 24, 25, and 26. The use of St. George's Hall has been granted by the Corporation, and numerous places for inspection and excursion have been partly arranged for, including Messrs. Blundell's collieries, near Wigan, and the Tubular Bridge at Menai Straits. In addition to papers on the manufacture and application of steel and iron, papers on subjects of work more immediately connected with Liverpool have been promised.

M. Janssen, we are glad to see, has been appointed to represent the Paris Academy of Sciences, at the inauguration of the statue to Arago, at Perpignan.

The prizes instituted by Prof. Schäfli (Lausanne) for scientific works on Switzerland will now be awarded not only to Swiss naturalists, as hitherto, but also to foreign, a resolution in this sense having been accepted at the last meeting of Swiss naturalists.

We regret to hear of the death of Mr. Edward Edwards, late of Menai Bridge, Anglesey, at the age of seventy-five. For upwards of twenty years he had studied the habits and characters of marine animals in their native haunts, and his contrivance of the "dark chamber tank" was the first by which these animal, could be kept alive and healthy for an indefinite period in confinement, and the principle of which was afterwards carefully recognised in the construction of the Crystal Palace and other aquariums.

The *Times* Geneva correspondent writes, under date August 22:—"On the evening of August 5, six persons who were standing in the gallery of a *châlet* in the Jura, above St. Cergues, witnessed an atmospheric phenomenon equally rare and curious. The aspect of the sky was dark and stormy. The air was thick with clouds, out of which darted at intervals bright flashes of lightning. At length one of these clouds, seeming to break loose from the mountains between Nyon and the Dôle, advanced in the direction of a storm which had, meanwhile, broken out over Morges. The sun was hidden and the country covered with thick darkness. At this moment the pine forest round St. Cergues was suddenly illuminated and shone with a light bearing a striking resemblance to the phosphorescence of the sea as seen in the tropics. The light disappeared with every clap of thunder, but only to re-appear with increased intensity until the subsidence of the tempest. M. Raoul Pictet, the eminent chemist, who was one of the witnesses of the phenomenon, thus explains it in the last number of the *Archives des Sciences Physiques et Naturelles*:—'Before the appearance of this fire of St. Elmo, which covered the whole of the forest, it had rained several minutes during the first part of the storm. The rain had converted the trees into conductors of electricity. Then, when the cloud, strongly charged with the electric fluid, passed over this multitude of points, the discharges were sufficiently vivid to give rise to the luminous appearance. The effect was produced by the action of the electricity of the atmosphere on the electricity of the earth, an effect which, on the occasion in question, was considerably increased by the height of the locality, the proximity of a storm-cloud, and the action of the rain, which turned all the trees of the forest into conductors.'"

A young female gorilla is now being exhibited at the Crystal Palace.

At the last meeting of the Swiss Naturalists, Prof. Kollmann (Basel) presented a report of the Anthropological and Statistical Commission, appointed by the Swiss Natural History Society for the investigation of the distribution of the light-coloured and dark-coloured population in Switzerland. Thanks to the collaboration of many schoolmasters, no less than 250,000 children in twenty-one cantons were described as to the colour of the eyes, hair, and skin, and a very rich and reliable material was collected. It is proved that in Switzerland, as well as in all middle Europe, the light-coloured population decreases from north to south, while the dark-coloured increases, and that it reaches its greatest quantity in the Graubünden, sending a rather dense branch to the south-west. It may be concluded that a dark-coloured population immigrated in Switzerland from the south, having also a side-branch which followed the direction from the Rhone to the Rhine.

We are glad to learn that the great undertaking of printing and publishing a catalogue of the Advocates' Library, Edinburgh, which has been in progress for many years, is now approaching completion. The Library of the Faculty of Advocates ranks next to the British Museum and the Bodleian among the libraries of the United Kingdom. It contains about 262,000 printed volumes, besides manuscripts of great interest and importance. It has had (under the Copyright Act) since the reign of Queen Anne the right of receiving a copy of every book published in the United Kingdom. Last year there were added to the Library 4,007 volumes of books, besides periodicals, pamphlets, and

music. The Catalogue consists of six volumes and supplement —containing over 200,000 entries—and extending to more than 5,500 quarto pages in double columns. Some idea of the expense of making and printing such a catalogue may be formed from the fact that individual Members of Faculty have already contributed, in donations and subscriptions, a sum of 3,700*l.* About 250*l.* are still required to print the supplement. It is expected that the work will be completed in September next, and the Advocates' Library will then be the only great library in the world possessing a complete printed catalogue. The value of this work will consist not merely in its making known the peculiar treasures of the library, but in its being the only approximately complete catalogue of all works published in the United Kingdom since the reign of Queen Anne, arranged not merely in the alphabetical order of the authors' names, but to a considerable extent also under leading subjects. Further, more information will be found in it on anonymous and pseudonymous English and Scotch literature than in any other catalogue; and a more extensive analysis of historical and other collections than can be had anywhere else. As regards biographical information, there will be found under each author's name cross-references to all books in the Library written about him or his works. We believe the Library has also a fair collection of scientific works. A copy can be had by addressing "The Keeper of the Advocates' Library, Edinburgh."

IT is with pleasure that we announce the completion of the second edition of "Die Urwelt der Schweiz," by Oswald Heer. Herr Schulthess, of Zurich, is the publisher.

IN its *Jahresbericht* for 1878 the "Bienenwirthschaftliche Hauptverein im Königreiche Sachsen" publishes the following highly interesting statistical data referring to the indirect utility of bees:—It has ever been one of the objects of all apicultural societies to prove the great importance of bees to agriculture generally. It appears that the Society named possesses 17,000 hives from each of which 10,000 bees fly out daily, which represents a total of 170 millions of bees. If we suppose that each bee undertakes but four journeys per day and that this takes place only on 100 days out of the 365, then we obtain a yearly total of 68,000 millions of bee-journeys. It is not too much to suppose that fifty flowers are visited on each journey, and we are certainly justified in supposing that five out of these fifty are fertilised; then we get a grand total of 340,000 millions of fertilised flowers per year. Let the value of fertilising 5,000 blossoms be but 1 pfennig (or 500,000 for 1*s.*), then the work done by bees of the society represents a value of 68 million pfennige, or 34,000*l.* sterling. It results from these calculations that each hive benefits agriculture to the amount of 2*l.* annually, a value which hitherto has been totally overlooked.

NEWS from Moscow states that a kind of subterranean conflagration is raging upon the islands and the shore of the Kurgaldschin lake in the district of Akmolinsk, province of Atbosarsk. It began in April last, and in the middle of June was still burning with unabated force. The fire spreads in the foot-deep layers of dry reeds, and has penetrated as far as the winter camps of the Kurgaldschin Wolostg, where some 120 Kirghise farms have perished through the flames.

AN international special exhibition of agricultural machinery, &c., will be held at Prague from September 27 to October 5 next.

THE well-known geologist Prof. Credner, has recently proved that in the western part of Saxony glaciers have formerly existed, by the discovery of numerous polished and grooved surfaces of porphyry rocks, now imbedded in the inundation deposits of more recent geological periods. From this discovery it seems that the Scandinavian ice at some epoch reached as far as the neighbourhood of Leipzig, *i.e.*, to the southern border of the North German plains.

NEAR Wildeshausen (Oldenburg) a so-called window-urn has been found in a prehistoric sepulchral mound. The urn is of elegant shape, perfectly smooth, only ten centimetres in height, and consists of bright gray fine clay. In the body of the urn there are three round holes of about two centimetres in diameter; into these holes green pieces of glass were let in when the clay was still moist. Another piece of glass is in the foot of the urn. Inside the urn stood a vase of the same material and almost the same height. The contents were bones and charcoal. Up to the present, as far as is known, only six window urns have been found; the one described would therefore be the seventh.

MR. MORRIS's recipe for the cure of the coffee-leaf disease in Ceylon appears to be the application of caustic lime in the proportion of two or three parts to one of flowers of sulphur. He maintains that the disease can only be successfully treated at one of its three stages—the filamentary—when the mixture described will kill the filaments. Mr. Morris is about to publish a handbook on the treatment of this scourge of the island, and by latest advices it appears probable that, at the earnest request of the planters, his departure from Ceylon to Jamaica will be indefinitely postponed.

THE *Echo du Japon* states that the works established at Tsukudu-shima for making carbonate of lime are proving very successful, and will, it is said, send a great quantity of the product to China.

NEAR the village of Eisenkappel (Carinthia), at the border of a forest, several new mineral springs have been discovered about the end of July. They originate in the bed of syenite granite which passes in the direction from Ebriach to Schwarzenbach, and are particularly rich in carbonate of soda, as well as in free and dissolved carbonic acid.

WE notice a very useful Russian pamphlet by M. Lukashevich, on arrangements for heating and ventilation, being a critical description of the various heating and ventilating apparatus exhibited at Cassel in 1877, during the first international exhibition of these apparatus. When we take into consideration how much remains to do in that branch of our knowledge, we cannot but welcome every good work on the subject.

THE *Report and Transactions* of the Cardiff Naturalists' Society for 1878, contains several scientific papers creditable to the members. The Society's Museum has been much improved.

A VOLUME of some interest in connection with progress in Spain has been published by Prof. A. Calderon Arana, "Movimento Novisimo de la Filosofia Natural en España." It is published at the Casa editorial de Medina, Madrid.

THE additions to the Zoological Society's Gardens during the past week include a Guinea Baboon (*Cynocephalus sphinx*) from West Africa, presented by Mr. P. Lembery; a Bush Dog (*Icticyon venaticus*) from British Guiana, presented by Mr. J. Ernest Tinne; a Ring-necked Parrakeet (*Palæornis torquatus*) from India, presented by Mrs. Watson; a Common Cuckoo (*Cuculus canorus*), British, presented by Mr. J. Sharpland; a Common Barn Owl (*Strix flammea*), British, presented by Mr. H. Norris; a Chacma Baboon (*Cynocephalus porcarius*) from South Africa, deposited; four Common Spoonbills (*Platalea leucorodia*), European, eighteen Chestnut-breasted Ducks (*Anas castanea*), an Adelaide Parrakeet (*Palæornis adelaida*) from Australia, purchased; a Cape Buffalo (*Bubalus caffer*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

DR. JOHANN LAMONT.—The death of Dr. Lamont, so long connected with the Royal Observatory of Munich (Bogenhausen), was mentioned last week. He was of Scotch extraction, and was born at Braemar on December 13, 1805. He was at first assistant at Munich, under Soldner, and was appointed director of the observatory in 1835, and Professor of Astronomy in the University of Munich in 1852. His name has, perhaps, been chiefly associated with terrestrial magnetism, his first publication on this subject being the "Handbuch des Erdmagnetismus," which appeared in 1838. In 1851 he wrote on the ten-year period of magnetic declination, of the existence of which he was an independent discoverer, and the same year he published at Stuttgart his "Astronomie und Erdmagnetismus," and a long series of memoirs bearing upon magnetical science is due to him. He is also the inventor of a set of instruments for determining the magnetic elements very widely used by continental magneticians. As an astronomer we find him occupied with the observation of Halley's comet with the refractor of eleven inches aperture, erected in 1835, by means of which he was able to follow the comet until May 17, 1836, nearly a fortnight later than it was seen by Sir John Herschel, with his 20-feet reflector, at the Cape of Good Hope, the last glimpse of the comet being thus obtained by Lamont. It was then distant from the earth 2·69, and from the sun 1·86, so that the intensity of light was almost precisely the same as when the comet was first detected by Dumouchel at Rome, August 5, 1835. In 1836 he calculated elements of the Saturnian satellites *Enceladus* and *Tethys*, which had been observed at Munich, and also discussed Sir W. Herschel's observations of the latter. In the summer of this year he measured the diameter of Pallas, and formed charts of stars in the clusters in Scutum and Perseus. In the following year he made a series of measures of the two brighter satellites of Uranus, and deduced from them a value of the mass of the primary considerably less than that previously adopted from Bouvard's tables. The most extensive astronomical work executed at Munich under Lamont's direction is the observations of zones of stars from + 15° to – 30° published in successive volumes of the *Annalen der k. Sternwarte bei München*, and in the previous series; various catalogues founded thereon, and containing together upwards of 30,000 stars reduced to the year 1850, have been published in the supplementary volumes of the Annals. Mr. Hind found in Lamont's zones two observations of Neptune before its planetary character was recognised. The magnitudes of the telescopic stars in these zones will prove serviceable from time to time in the investigations of the periods of variable stars.

THE SATELLITES OF MARS.—Prof. Asaph Hall, after discussing the long series of observations of the newly-discovered satellites of Mars made with the Washington 26-inch refractor in 1877, expressed the opinion that at the approaching opposition of the planet these objects will be observable with that instrument from about October 10 to November 29. It may therefore appear almost hopeless to expect measures as early as September, yet probably efforts may be made in this direction and with the view to facilitate the identification of the outer satellite, *Deimos*, we subjoin positions calculated from Prof. Hall's elements for 13h. Greenwich mean time :—

	Pos.	Dist.		Pos.	Dist.
	°	"		°	"
Sept. 11	235·5	48·5	Sept. 16	238·7	46·5
12	296·3	10·3	17	8·5	12·7
13	49·9	46·9	18	53·1	51·7
14	68·3	30·0	19	80·0	19·8
15	221·6	33·2	20	227·1	43·6

The greatest elongations of the satellites occur at angles of about 53° and 233°, the greatest apparent distances at the next opposition being 67" for *Deimos* and 27" for *Phobos*, the former passing the extremity of the minor-axis of the ellipse about seven seconds distant from the limb of the planet.

GEOGRAPHICAL NOTES

HERR OTTO SCHÜTT, the well-known African traveller, has returned to Lisbon from his exploring expedition to Central Africa, undertaken by order of the German African Society, and has delivered an interesting lecture to the Lisbon Geographical Society. He brings home highly important and quite new data concerning the complicated hydrography of the Congo Basin. Between the Cuango and the Casai rivers, two known tributaries of the Congo, he has discovered four others, viz., the Quengo, Marata, Cinlu and Quanger rivers. Besides this he has determined the upper course of the Casai river from lat. 8° S. to about lat. 6° S. in a district totally unknown hitherto. From lat. 8° S. as far as lat. 4° S. the Casai takes the name of Zaïre, which on older maps is often given to the Congo itself. The lake called Sankowa Lake by English explorers is situated in lat. 5° S., and is called Mucaruba by the natives. To the south of this lake a tribe of dwarfs are living. The tribes inhabiting the shores of the Quengo and the Casai rivers are cannibals. As the Muata Jamvo, who some three years ago stopped Pogge's further progress, did not permit Herr Schütt to cross the Lulua river, he had to return to Loanda on the west coast.

IT is announced from Sierra Leone that Mr. H. M. Stanley arrived there on July 24, and left on August 1 for "Banana" (? Mboma), on the Congo.

INTELLIGENCE has been received at New York of the arrival of the Polar exploring vessel *Jeannette* at Onalaska, on the 2nd inst. She is to endeavour to meet with Nordenskjöld in Behring Strait. The United States Revenue vessel *Richard Rush* has passed through Behring Strait, within seventy-five miles of East Cape. Her captain reports that the sea northward of that point is clear of ice. Last winter had been unusually warm, and the ice broke up earlier than usual.

SEVERAL Russian expeditions are to be sent out during this autumn to Central Asia, and especially to the Darwaz. Capt. Hermann and the well-known young botanist, M. Smirnoff, will explore that quite unknown country, and M. Smirnoff will no doubt bring back a rich botanical collection.

A TELEGRAM has reached St. Petersburg through Pekin from Col. Prjwalsky, to the effect that at the date of his despatch his expedition had accomplished the third part of the route to the Himalaya, and that no great obstacles were expected to intervene between them and their desired goal—which may mean Lhassa.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

How did Eozoon Originate, and is Graphite a Proof of Organic Beings in the Laurentian Period?

I READ with great interest the abstract of Dr. Moebius's investigations on Eozöon in NATURE, vol. xx. pp. 272, 297, and no more doubt of its inorganic origin. But how was Eozöon formed? We find such single or ramified foraminiferæ-like or algæ-like fibres or stems (Figs. 5, 9, 10, 18, 19), which show,

by their irregularity, that all organic origin is excluded, sometimes in ice; they originate in the hardening together of crystals, under pressure, and are only the imprisoned, often stem-like and branded hollows of air. Like Eozöon they become afterwards filled with foreign matter, with serpentine and chrysotile, resulting out of the watery decomposition of olivine.

To show how analogous circumstances are also applicable to the origin of Eozöon, I shall first refute the two erroneous arguments often adduced for the organic existence in the laurentian period: the presence of graphite and the stratification of the oldest rocks.

Graphite, as Dr. Moebius supposes, cannot be a sign of primitive organic life. (1) In the oldest period there certainly lived only the most primitive lower beings, which without exception decay rapidly, and are therefore not able to furnish coal. (2) Graphite is sometimes a substitute of mica in the Gneiss; if it be phytogen, the synchronous quartz and feldspar, &c., must also be declared so; but that is absurd. (3) We always get amorphous coal out of organic beings, and by chemical process in the cold way, and on the contrary crystallised coal, *i.e.* graphite, is only to be produced by heat, and in several ways, even out of gases. We must regard graphite as one of the arguments, proving the incandescent origin of the oldest rocks. Out of each kind of coal, also of graphite, bitumen can originate, so that bitumen is not always a sure proof of organic beings. (4) There exist many other facts proving the incandescent origin of laurentian minerals; I will add, as I believe, a new one. This origin excludes at the same time any living beings. Not one original mineral of the laurentian minerals contains water, only mica contains a very small proportion, but this chemically combined, for it cannot be expelled at red heat. If these minerals had not had their origin in heat, they would sometimes contain water.

The other fallacious proof for the neptunic origin of laurentian rocks is their occasional stratification, and this origin would include the possibility of organic beings. No geogenetic hypotheses have been able to combine the facts of heat origin and stratification! But if we change the generally adopted opinion of Kant and Laplace, that the gases of the atmokosmos formed our globe by being condensed first into incandescent liquids, and finally into *crystals*, we may combine all the facts.

It is often found that we get out of hot gases mostly crystals, which partly by chemical reaction, become at first incandescent, and even quartz, feldspar, granite, and some iron minerals that we find in the granite, are known to be produced crystallised out of gases. Other facts prove that these laurentian minerals must have originated between white and red heat.

In the origin of glaciers we have an analogy for the agglomeration of the incandescent crystals into the first earth-crust without melting, only by baking together, as being somewhat plastic, the crystals of snow harden together into ice, driving out the air between the crystals and loosing their crystallised surface, assuming also sometimes Eozöon-like forms. Glaciers not seldom show stratifications, especially in the upper part formed by temporary snow-falls. As on the top of the glacier the snow-crystals lie yet ununited, so the minerals of the laurentian period were certainly lying ununited upon the surface, and became afterwards hydrated together, when the earth-crust was cool enough, so that we find them in the post-laurentian period much more mixed and with products of neptunic erosion. OTTO KUNTZE

Leipzig-Eutritzsch, August 2

Unobserved Impressions

A NOTE to Mr. Mivart's address in the Biological Section of the British Association contains the following:—

"Having gazed vacantly through a window we revert to the pages of a manuscript we may be writing and see there the spectra of the window bars we had before unconsciously seen. Here the effect on the organism must have been similar to what it would have been had we attended to it—*i.e.*, it was unfelt sensation" (NATURE, vol. xx. p. 399).

The last words induce me to mention what I believe I have often observed but have hitherto presumed to be well known in psychophysics, because though they are not inconsistent with it they seem to show that it had escaped the speaker; namely, that an unobserved impression produces a much stronger effect on the organism immediately impressed than an observed impression. Of course the observation cannot be experimentally prepared; but if any one who experiences a case like that described by Mr. Mivart will allow the image to fade and then try to form another of the kind, he will be struck I believe by the inferiority of the voluntary one.

The phrase "unfelt sensation" suggests questions I wish to keep clear of; but the phenomenon appears to me interesting, because it plainly shows that work which would be done on the retina, or on something, by an unobserved impression, is done elsewhere by an observed one. C. J. MONRO

Chesterfield, August 24

Insect-Swarms

A WONDERFUL flight of insects has passed over here to-day, consisting of the butterfly *V. cardui* and the moth *P. gamma*. They all came from the sea from the north-west and passed over the land to the south-east. I first noticed the flight at 7.30 A.M. The morning was bright and sunny with a light wind a little south of east. Great numbers of *V. cardui* were soaring at all heights, up to at least 150 feet, above and between the poplars which surround the house in which I am staying; all were going leisurely to the south-east; lower down *P. gamma* more erratic in its flight, was going in numbers in the same direction. I went down on to the grassy slope above the shore cliff. The blackberry blossoms were covered with *V. cardui* and *P. gamma*, three or four ou a flower, the fussy moths much disturbing the more sedate butterflies, but each bent on holding its own. With scarcely an exception they took flight in a south-east direction when disturbed or when satisfied with their often, I fear, vain search for food. I stepped fifty paces from a clump of dark firs at right angles to their line of flight and counted the butterflies which passed for two intervals of two minutes; the numbers were 95 and 108, but I probably missed some of the higher ones. On the shore at 10 o'clock I counted 73 in one minute pass a space 50 paces in width; at 11.45 in one minute 50 passed the same space. The numbers of *P. gamma* were more difficult to ascertain owing to their smaller size and more erratic flight, but as they all flew very low on the shore, not more than a foot or two at most above the water or sand, I stepped 20 paces and tried to count the moths passing within those limits with the result—one minute 32 moths, two consecutive minutes 18 moths, again two minutes 120 at least. In the second interval a strong gust of wind checked the flight altogether, and in the third interval the moths came so fast that I missed many I feel sure. The *P. gamma* were evidently much exhausted; while bathing I saw several floating on the surface of the water, which took flight when touched or crawled on to a finger presented to them; some settled on me and on others while we were bathing. At 12 o'clock I passed uninterruptedly through the flight while walking from Trouville Harbour for a distance of two kilometres northwards along the shore. There was then an occasional white butterfly (*Pieris*) in the flight, and I also noticed two dragon-flies coming from the sea and following the same direction as the other insects; I noticed other dragon-flies with the flight inland, but they abound here. Had those coming from the sea accompanied the flight throughout as hawks are said to follow the flights of birds on which they prey? From the shore I climbed up the cliff, the grassy slopes above it were swarming with *P. gamma* and *V. cardui*, nearly every flower having one visitor at least. At 1.15 P.M. *P. gamma* passed over in undiminished numbers, but *V. cardui* was not so abundant. At 5.30 I rode parallel with the coast line along the Honfleur road to a point rather more than 10 kilometres from Trouville, passing through an uninterrupted flight of *P. gamma* all the way, but no *V. cardui*, though the butterfly still abounded on the blackberry and other blossoms by the roadside. Throughout the last two kilometres the moths were much fewer in number, but had not quite disappeared when I turned back. *P. gamma* generally flew lower than *V. cardui*, but the force which impelled them in one direction, as if their bodies were magnetised and their north pole was in the south-east, was so strong that when they met an obstruction to the course of their flight they went often over it not round it. While riding I noticed that they rose up and flew over isolated buildings, and I was curious to see whether they would do the same with a church tower. As I passed through Villerville, three came over the top of the church tower, and again at Criquebœuf, three fluttered up the wall, and flew over the church tower as I passed it. At 8 P.M. I went up on to the roof of the house; the moths were then flying up the front of the house and over the roof in great numbers. The flight of *P. gamma* continued to pass the

house in which I am writing, without interruption, from 7.30 A.M. till dark, and are now at 11.30 P.M., flying in at the open window, so as to be a perfect nuisance. They are still tired moths, for they soon settle; there are certainly many hundreds in the dark corners and along the cornice.[1] My children tell me that numbers of the moths were lying dead on the dry sand above high-water mark.[2] They collected some for a tame young magpie, which has been very happy all day among the flower-beds in the garden catching *P. gamma*, which, under ordinary conditions, would be far too wide awake for him.

How far the flight extended south of Trouville I do not know, but the number of insects which have passed from sea to land here to-day must be very great. Assuming that one *P. gamma* passed over each metre of shore line each minute, an estimate below the mark at all points to which my observation extended, and assuming the flight to have extended 10 kilometres along the shore, as I ascertained that it did during the evening, nearly 8,000,000 of *P. gamma* passed from sea to land between 7.30 A.M. and 8.30 P.M.

All the insects which I caught or looked at on flowers were in perfect condition.

Where have all these insects come from? Has the flight been noticed in England? *V. cardui* was exceedingly abundant here in June and throughout July, indeed it was the only butterfly to be seen in any numbers. Its larvæ have been feeding in tolerable numbers on the thistles and other plants, and some few fresh specimens appeared before the flight of to-day, but I think there is no doubt the insects which formed to-day's flight were not bred here. Why should the moth and the butterfly come together? Here they were flying against or nearly against, the wind, although they may have started with a favourable wind. Where will they go to? If they go far, what influence will they have on cross-fertilisation? The quantity of pollen which they will carry onwards from the myriads of flowers they have visited will be immense. Perhaps other observers may answer some of these questions. J. CLARKE HAWKSHAW

Trouville, Calvados, France, August 12

P.S.—The flight still continues this morning, August 13, 10 A.M.; *V. cardui* quite as abundant as yesterday.

P.S. No. 2.—The flight of *V. cardui* and *P. gamma*, described in my letter of August 12 ceased about 12 A.M. on the 13th. At 11 A.M. I counted forty-six and twenty-four *V. cardui* on the shore passing over a space of fifty yards in width, in two intervals each of two minutes. Judging from their number, the *V. cardui* have not remained here; on the other hand, I think many of the *P. gamma* have. On the 14th a large clearing in the forest of Tonques, about two miles inland, was alive with them. The flowers of the wood-sage appeared to be the great attraction there. I noticed many *P. gamma* lying dead on the roads inland, all in perfect condition. I believe that these moths died of starvation. The moths which flew into the house on the evening of the 12th were all more or less sluggish in the morning. There were more than 400 on one window, many of which readily took food offered to them in the form of syrup, and I induced a number of those in the forest to come on to my finger and suck up syrup.

What I have seen leads me to make the following suggestions as to the cause of these migrations of lepidoptera.

When a favourable season produces a great swarm of insects numbers would die from want of food if they remained where they came into existence, as the number of food-producing flowers is limited. To move off in some direction would be a necessity, and in time the impulse to migrate would become instinctive as soon as the want of food was felt, or even the presence of a crowd of their fellows. It would seem that the supply of food might be most readily found if the insects moved off in all directions, that is, spread from the centre of scarcity; but many moths seek their food by scent, and on that account generally, I believe, fly against the wind. Many facts might be given to show how acute the power of scent in moths is. Whether butterflies seek their food by scent or not I do not know; some are certainly attracted by strong odours, *Apatura iris*, for instance. At any rate, I think a hungry moth would fly against the wind, and so the general direction of a flight of moths might be determined.

Here both butterflies and moths searched the first flowers they came to after leaving the sea. The first comers would go on refreshed, but the later ones merely wasted their energy in a fruitless search, and many of the moths fell dead by the way.

In the case of the flight I have described, a double necessity for the migration would have arisen if the butterfly and the moth came into existence at the same time as, seeing their fine condition, they most probably did. As both appeared to search the same flowers, the dearth of food at their centre of departure would more speedily have arisen.—J. C. H.

August 23

[1] I have counted 200 on one part of the cornice.

[2] Possibly killed by the heat of the sand, on which they settled in an exhausted state.

Animal Rights

MR. ROMANES's parallel is as unsound as amusing. If a physiologist claimed to vivisect his children "on the plea that it was for this purpose that he had begotten them," we should tell him that the legal admission of such pleas would undermine human society. But in the killing of pigs for food no undermining of human society is involved. Moreover, we know that men breed pigs only to kill them, but that men breed children from entirely different motives; we should answer the physiologist that his plea was impossible of proof, that all human experience negatived its probability, and that consequently it could not be admitted to overrule his children's presumptive right of life.

Mr. Romanes repeats his amazing proposition in morals, that "if we have a moral right to slay a harmful animal in order to better our own condition, it involves an inconsistency to deny that we have a similar right to slay a harmlesss animal, if by so doing we can secure a similar end." Then, if we have a moral right to slay harmful Zulus to better our own condition, we have a similar right to slay harmless Eskimos, if by so doing we can secure a similar end!

Mr. Romanes says that I did not attempt to meet one of his criticisms. Had I thought I might, I would have met them all; it does not take long. He thinks a lobster, to whom might is right, could not convince a philosopher that the latter had no right to eat him. Then I may pick a thief's pocket? He next admits that the lobster might appeal to the philosopher's morality, but asks why "the right of an edible animal to live is superior to that of an eating animal to kill?" Then the right of a robbable man to his money is not superior to the right of a man who uses money to rob him? And I, who am edible, have no more right to live than a cannibal has to eat me? Lastly, Mr. Romanes makes his philosopher say that he prefers lobster salad and roast lamb to boiled snakes and rat pie. Preferences are not rights, but if they were I have not suggested that the latter diet should supersede the former; and so my withers are unwrung.

EDWARD B. NICHOLSON

[*Ergo* the rights of a pig are *not* the same as those of a baby, which is just the point which my purposely unsound parallel was intended to show. It is for Mr. Nicholson to prove that the parallel is *sound*, if he is to sustain his "erroneous premiss," that the rights of men and animals are identical (the objection as to "motive" I ignore, because on the erroneous premiss in question the physiologist's motive might be sincerely stated and adequately proved as *a* motive by a declaration, say, in the marriage settlements). Instead of doing so, however, he alludes to one important difference between the rights of an animal and those of a man—the difference, namely, which arises from the latter being a member of human society. And this difference is in itself sufficient to nullify the force of all his rejoinders. Only on Mr. Nicholson's own supposition, that the rights of all living things are identical, could any of my propositions made with reference to animals be tested by their applicability to men. But this is just the supposition which I regard as absurd, and because it seems to me that ethical doctrine is here sufficiently patent—viz., that man as an intellectual, moral, and social being has rights additional to those of a merely sentient being. I will not take any further part in this correspondence.]

GEORGE J. ROMANES

Alpine Clubs

IN your account of the late conference of Alpine clubs, held at Geneva, there is one little omission which, as interesting to the scientific world generally, I beg leave to remedy.

It was suggested by your humble servant that a re-publication of de Saussure's "Voyages dans les Alpes" would be an appropriate memorial of our little congress at the city of which he was, I may say yet is, so bright an ornament. My plan was to

add the matter necessary to bring his work up to date in science, within square brackets (as in Stephen's edition of "Blackstone's Commentaries"), or as notes, or even as an appendix, the whole work to be in the hands of an efficient committee. The proposition was very cordially received, and I should like to hear what English men of science think of the matter. The book is of the freshest, brightest nature; even as a small boy I delighted in it; and my own idea is that de Saussure, though necessarily behind the giant strides of modern knowledge, made so very few mistakes that re-publication would not have the same dangers for his reputation as it might for that of a mere mediocrity.

MARSHALL HALL

Vernex-Montreux, Canton Vaud, Switzerland, August 19

"Report of an Unusual Phenomenon Observed at Sea"

I CAN supply a second instance of the "unusual phenomenon observed at sea," communicated by the Hydrographer of the Navy to NATURE, vol. xxi. p. 291.

One night in April, 1875 (I cannot give the exact date, as my notes were lost in the ship) H.M.S. *Bulldog* was lying becalmed in a glassy sea off a point of land a few miles north of Vera Cruz, when a line of light appeared along the northern horizon, and unaccompanied by the least breath of wind, swept towards and past the ship, in a series of swift luminous pulsations, precisely similar to those described by Mr. Pringle. Acting on the old sea formula, "observed a phenomenon, caught a bucketful," we dipped up some of the water, and found noctilucæ and crustaceans in it. These may have supplied the luminosity, but if so, the exceedingly swift-travelling cause of their stimulation would still remain unaccounted for.

A squall accompanied by incessant thunder and lightning overtook the ship the same night.

EDWARD L. MOSS

Rathgar, Dublin, August 19

Boring Molluscs

THE following extract from Prof. Joseph Leidy's paper on "Vertebrate Remains, chiefly from the Phosphate Beds of South Carolina," which appeared in NATURE, vol. xx. p. 354, will serve in aid of the solution of the still open question, By what means do the boring molluscs penetrate hard rocks?—"The fossils mainly consist of the harder parts of the skeleton and of teeth, usually more or less water-worn, indicating shallow seas and an active surf to which they were exposed. Many of them exhibit the drilling effects of boring molluscs, especially those which are supposed to have been derived from the tertiary marl rock, the operation of drilling apparently having been performed both before and during the time the fossils were imbedded in the rock. Only enamel, or the enamel-like dentinal layer such as is found investing the crown of the teeth of sharks, appears to have been a protection against the drilling power of the borers."

Were the burrows produced by the solvent action of an acid, there is no reason why the enamel should have arrested the solvent rather than the dentine, although it might yield more slowly to it; but its refractory behaviour under friction accounts for the Pholades and Teredines being nonplused; while their desistance from fruitless efforts affords an instructive example of pure *instinctive* action, *i.e.*, reflex action "the prompting to which is given by sensations."

PAUL HENRY STOKOE

Beddington Park

Intellect in Brutes

A CORRESPONDENT of yours tells a tale (NATURE, vol. xx. p. 338) about a cat ringing a bell to be let in. Without any wish of "topping" this tale, I think the following will go far to demonstrate the existence of a thinking power in the brute brain, if indeed that fact is ever doubted:—

Some relatives of mine living in Sussex owned a very intelligent dog of somewhat doubtful breed, having, however, a decided touch of the French poodle in his composition. In addition to this animal they also had a favourite cat. For some time they were bothered in the way your correspondent describes by runaway knocks, instead of rings, as in his case; however, they discovered that the cat had learnt to stand on her hind legs and reach the knocker which was low on the door, and to knock distinct and separate double knocks until she was admitted. This in itself was curious, but a short time after they discovered this fact they discovered another still more curious. They were in the habit of turning the dog out every evening for an airing. It invariably happened that if the cat was out of the house at the same time, that a short time after the dog was turned out they would hear a knock at the door. On its being opened both animals would be found outside and would immediately come in, the dog always allowing the cat to precede him. There seems to be no doubt that the dog finding out that the cat could obtain entrance was in the habit of searching for her when he wanted to come in, and either waiting till she was ready to knock at the door, or of inducing her to do it to please him. I can myself vouch for the above facts.

W. H. KESTEVEN

Holloway, August 13

MR. LAYARD's letter mentioning the bell-ringing cat leads me to send the following account of a wise old Scotch collie with which I was personally acquainted. Toby, belonging to my friend Mr. T. F. Hancock, formerly of Tyes Place, Staplefield, Sussex, was passionately fond of his vocation, but at the same time made much of in the parlour. On one occasion, while lying in front of the fire in the dining-room, he heard sheep going by the house along the farm-road. He ran to the window-seat and then to the door, at the same time looking imploringly at my friend's sisters, as if to beg them to let him out. This, however, they declined to do, and after one or two journeys between window and door, he ran to the long, old-fashioned bell-pull, rang the bell, stood at the door, and bolted out and round into the kitchen as soon as the servant appeared.

After this Toby was constantly employed during meals to ring the bell, and I have myself often made him perform the operation, which was always accompanied by a good deal of barking. My friend has a more than life-sized painting of this wise dog, painted by the late Charles Hancock, the animal-painter.

One more instance of reasoning I will relate. A few months ago my wife and I were bathing a cocker dog in the stream flowing through the grounds of St. Helen's, Cockermouth. We threw a croquet-ball into deep water, and the dog was to bring it to shore. But the ball was rather large for the size of her mouth, and as often as she snapped at it the ball glided away. After vainly endeavouring to grip the ball, we watched her suddenly give over, and begin pawing it with her fore-feet until she brought it into shallow water, when she easily made the capture, and brought the ball to the bank. The same was repeated several times. It is unnecessary to say that this was not the result of teaching.

J. CLIFTON WARD

Keswick, August 14

As your pages have for some time drawn attention to such inquiries, I wish to ask if any one ever saw a favourite dog, or other animal, stop to gaze at a rainbow? We have never heard of such a case; but if ever encountered a record in your pages is invited.

THE HUMAN SPECIES

The Human Species. By A. de Quatrefages, Professor of Anthropology in the Museum of Natural History, Paris. (London: C. Kegan Paul and Co., 1879.)

THERE is possibly no science which is so generally misunderstood, and yet has had so many works of popular exposition, as anthropology. It is but a few years ago that the works of Latham, Lawrence, Pickering, and Prichard formed almost solely the consulting literature of the science in this country; and without referring to the various standard works that have since been contributed on special branches of the subject by English workers, the exclusively English reader has perhaps been enabled to consult the translated works of continental anthropologists to a greater extent than has been the opportunity of the student in other fields of science. During the last fifteen years volumes of Blumenbach, Broca, Gastaldi, Peschel, Pouchet, Topinard, Vogt, and Waitz have appeared in this country in our own language, and now to the list may be added the work of the distinguished naturalist under notice, whose name, however, will be popularly remembered as the author of "Rambles of a Naturalist on the Coasts of France, Spain, and Sicily," which appeared in London in 1857.

Naturally, among the above treatises, there are to be found wide divergences of views, and perhaps the student of anthropology should be above all others careful to avoid the scientific extremes of either a Paul or Barnabas persuasion. It is, however, absolutely necessary that we should understand our author, especially that we should learn whether he approaches the consideration of the study of man with any preconceived notions, which may be peculiar to himself or not generally held by other thinkers. This M. de Quatrefages promptly discloses in the first division of his book, entitled "Unity of the Human Species," a subject which seems still somewhat of a burning question among French anthropologists. The question as to there being a fundamental distinction between man and other animals is settled in the affirmative, and for the following reasons:—

1. Man has the *perception of moral good and evil*, independently of all physical welfare or suffering.

2. Man *believes in superior beings* who can exercise an influence upon his destiny.

3. Man *believes in the prolongation of his existence after this life.*

Readers of Lubbock, Spencer, or Tylor will perhaps scarcely accept this as the philosophy at least of primitive man, but, in justice to M. de Quatrefages, we must endeavour to obtain his definition of the moral and religious stage, and this again is clearly set forth in the following sentence:—"The learned mathematician, who seeks by the aid of the most profound abstractions the solution of some great problem, is completely without the moral or religious sphere into which, on the contrary, the ignorant, simple-minded man enters when he struggles, suffers, or dies for justice or for his faith."

In discussing the different colours of mankind, melanism is considered to be the result of accidental variations, and is compared with that which, appearing in our poultry-yards from time to time, is only prevented from spreading by the destruction of the fowls attacked. It is a question, however, whether the occurrence of melanism in our poultry-yards is not often an instance of atavism, and it is probably incorrect to say (p. 49) that the flesh of black fowls presents a repugant appearance, and for this reason the propagation of the variety is prevented, when, as is generally well known, fowls of the black Spanish breed are greatly valued as table birds. This section concludes with a discussion of the vexed term "species," and, according to M. de Quatrefages, *knowledge of facts* preceded *terminology*, and his arguments compel him to the opinion that "species is then a reality." Without, however, going so far as to say with Goethe that species exist only in the copybooks of the specialists, is it not certainly a fact that the founders of zoological nomenclature and classification based their conclusions then, much as we do, and necessarily in zoological descriptions of to-day, on the general outward resemblance and structure of living forms, and that knowledge of facts more frequently follows terminology, as any well qualified and exhaustive monograph of an animal group that has been long worked and studied by zoologists of different views and methods will exhibit? Few ornithologists, in describing a new fruit-pigeon from abroad, are guided by the researches of Darwin on the multitudinous variations of the domestic pigeon at home; and as for the descriptive entomologist, he, at least, can hardly realise species as a reality with his present limited knowledge of the life histories of exotic insects. In a philosophic sense the word species, as a rule in zoological literature, is a useful biological conventionalism, as necessary but as difficult to rigidly define as the term atom, and often playing as valuable a part in classification or generalisation as the "imaginary quantity" of the mathematician fulfils in the course of his calculations. It is for these reasons that we have found a difficulty in following M. de Quatrefages in all the rigidity of his specific definitions.

The second portion of the work is devoted to the "origin of the human species." To the question whether it is possible to explain the appearance on our globe of a being "which forms a kingdom to itself," M. de Quatrefages does "not hesitate to reply in the negative." It is to be noted how such an eminent naturalist as our author is still opposed to Darwinism, which in this section receives copious treatment, and some of the grounds principally given for its rejection are to many minds who embrace it the reasons of their faith. "The positive knowledge which has been won by nearly two centuries of work" is not considered by Darwinists to be invalidated, but rather illuminated, by the light of "natural selection," and facts which were unmeaning before, now by its aid form one harmonious whole in an evolutionary cosmos. It is remarkable that the doctrine of "natural selection" appears to have been a greater stumbling-block to the French mind than might naturally have been expected, whilst in German thought it seems to have at once supplied a want. Is it that French biology has never cared to depart from the glory that illumines the work of the illustrious Cuvier, and, like other schemes of philosophy, remains true but riveted to the teachings of its founder? Even M. de Quatrefages recognises something of this, and speaks of "the reserve, perhaps exaggerated, which Cuvier imposed upon himself, and the confidence which was placed in

him" as having weighed heavily upon science by impeding the comprehension of the value of new observations.

In discussing the antiquity of man, the present geological epoch is considered with "almost absolute certainty" as having commenced less than 100,000 years ago, and the opinion is pronounced that no facts have as yet been discovered which authorise us to place the cradle of the human race elsewhere than in Asia. As to the appearance of primitive man, our author concludes that "all that the present state of our knowledge allows us to say is that, according to all appearance, he ought to be characterised by a certain amount of prognathism, and have neither a black skin nor woolly hair. It is also fairly probable that his colour would resemble that of the yellow races, and his hair be more or less red. Finally, everything tends to the conclusion that the language of our earliest ancestors was a more or less pronounced monosyllabic one."

Once in possession of these views of our author, we can with the greater advantage read the excellent summaries and descriptions which form a large portion of the work relative to migration, acclimatisation, and "fossil races"; but perhaps the most interesting are those devoted to the "Psychological Characters of the Human Species." These tend to show in a new sense the brotherhood of man, so that if political economy could be called the "dismal science," anthropology should be considered as the most cheerful of its learned sisters. M. de Quatrefages combats some of the views of Sir John Lubbock as expressed in his "Origin of Civilisation" with great force, and has some very useful reflections on the danger of attributing all sense of honesty as absent in certain races on insufficent data. "Nothing is more common than to hear travellers accuse entire races of an incorrigible propensity for theft. The insular populations of the South Sea have, amongst others, been reproached with it. These people, it is indignantly affirmed, stole even the nails of the ships! But these nails were *iron*, and in these islands, which are devoid of metal, a little iron was, with good cause, regarded as a treasure. Now, I ask any of my readers, supposing a ship with *sheathing* and *bolts* of gold, and nails of diamonds and rubies were to sail into any European port, would its sheathing or its nails be safe?"

In conclusion, though many parts of this work show that to the author Darwin must have lived and written in vain, and some of the portions appear as anthropology little advanced from the time of Prichard, we cannot but still feel grateful that the general literature of this little-known, but most necessary of sciences, should have been enriched by a useful though not infallible book.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Parthenogenesis in a Beetle

I DO not know whether any instances have been recorded of parthenogenesis in the coleoptera, nor does the interest of the case I am about to relate consist in the discovery of the operation of a not uncommon mode of insect reproduction in a new field, but rather in its altogether abnormal and fortuitous character in the species of beetle concerned, viz., *Gastrophysa raphani*. My own observations hitherto on this species have been uniformly to the effect that unimpregnated females lay always barren eggs, and that one intercourse with the male renders fruitful all eggs subsequently laid. I bred the female in question from the egg this year, and have kept her isolated since her exclusion as an imago. She has laid, up to the present, about twenty batches of eggs consisting of about thirty-four and fifty-one alternately in the batch. Of these, some fifteen batches have been observed; and only in one of these, No. 10, to wit, consisting of thirty-four eggs, and in one of these thirty-four only were any traces of development observed. This batch was laid between the 2nd and 4th of August. On the 5th I noticed in one an appearance which is usual about this time in fertilised eggs, which I have been accustomed to think about as the "embryonic scroll," and which, on reference to Huxley's "Anatomy of Invertebrated Animals," pp. 444–445, I am inclined to think may be what is there called "the *sternal band* (*Keimstreif* of the German embryologists)." This scroll is invariably present in gastrophysa eggs regularly developing, and enables one to predict with certainty the position of the ventral aspect, and of the head and tail of the future larva. On the 6th this same appearance was more distinctly marked. On August 10 a further well-defined stage of development had been reached. On the 11th the ocelli were plainly visible. Next day I noted the antennæ, mandibles, palpi, and legs. The segments, warts, and spiracles were also to be seen. On the 12th and some subsequent days I saw plainly somewhat feeble but unmistakable and decided movements of the legs, especially of the tarsi and ungues. At this season of the year the egg should have been hatched in about ten or twelve days. I have no longer any hope of this, and all larval movements appear to have ceased. All the other (thirty-three) eggs have undergone the usual degeneration, but this one presents a striking contrast to them, showing all the external parts perfectly formed and distinctly visible, as far as the position of the larva (which is just the reverse of the usual one, namely, with the dorsum in place of the venter next the surface of attachment) allows them to be seen. There is an unusual appearance of brownish coloration towards the caudal end, the nature of which I have not made out. The failure to hatch out, however, does not hinder this from being a decided case of embryonal development in an egg laid by a female of *Gastrophysa raphani* whose virginity is assured; and it is a solitary instance occurring among some eight or nine hundred eggs laid by the same beetle both before and after and along with it, all of which (as far as observed) were normally and uniformly barren.

J. A. OSBORNE

Milford, Letterkenny, August 18

Fonts in the Rocks of Brook Courses

I BELIEVE the present an opportune time to direct the attention of geologists to the occurrence of water-graven *fonts* in the rocks of brook courses, as the season of field-work is come, and the summer conditions of our water-courses facilitate observations of this most curious and interesting, as well as deeply important, of river physics.

So long ago as two years, examining the rocks bared on a river channel for the purpose of making a section, I found *fonts* in the rocks over which the waters run (in Slievardagh coal-field, Tipperary). I had not previously known of their occurrence. Those I first found I then looked on as something exceptional, but as my investigations extended and as I learned to recognise the conditions under which *fonts* are graven, I found them to be pretty general in streams having rapid descents. Nor do I think their occurrence is generally known and noted by geologists and physicists. I have seen in print but one allusion to them—in NATURE, vol. xix. p. 76, where they are notified as observed in a river in East Africa during the dry season as a "noteworthy peculiarity."

In what hereinafter appears, I do not at all mean to question the theory given as explanatory of the large "well-like basins" on the African river; doubtless our traveller had his good reasons for his conclusions.

The mode of occurrence of these fonts in the Slievardagh brooks is, I venture to submit, as follows:—They are graven in the rocks by falling waters; these waters being the main stream,

a portion (and it may be a diminutive quantity) locally detached from the main stream, or a feeder dropping into the main stream from steep, rocky sides. This is the primary cause. But along with the presence of a graving machine in the falling waters, to explain the making of the fonts a concurrent cause is necessary, as otherwise they should be looked for anywhere and everywhere on rapid descents. The conducive condition is the coincidence of falling waters with a *weakness* of the rock, such as an intersection of the division planes or fissures. I have secured a specimen font, 10 inches deep and 12 inches width across the bell-shaped mouth, in compact siliceous rock graven by a diminutive shoot of the main stream running down the depression which generally marks the edge of a division plane till it reached an intersection; at the intersection it graved a font, and issuing from this went on to the next, and there graved another (see sketch, Fig. 1). The stream, flowing round and kept up by a bed of rock dipping approximately in the direction of the current, overflows in flood-time, or generally except in dry summer weather, down the fissure A B; at the intersections the fonts were graven, and the water on leaving the lower one runs along the edge of a superposed bed. We are now bound to seek a limiting condition, as otherwise almost every pool into which there

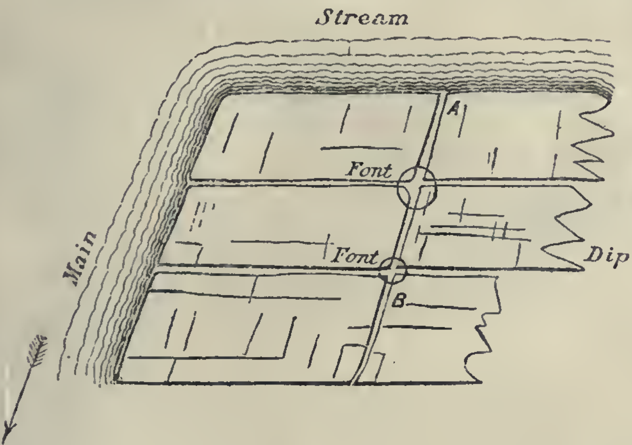

Fig. 1

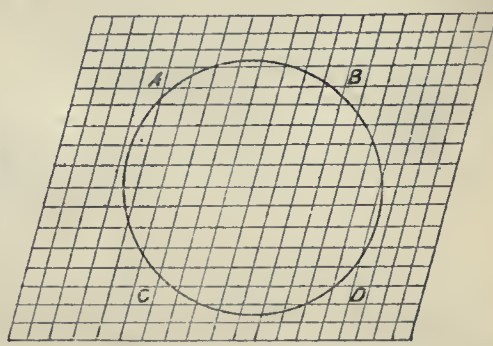

Fig 2

is a waterfall might reasonably be expected to be a font. The limiting cause is the relation between the size of the blocks into which the rock is divided and the graving power of the falling waters. If the waterfall is sufficient to grave a font of over a certain size in rocks broken by planes into blocks of a certain size, the consequence is that the whole blocks or blocks by fragments will be broken away, and the walls will be the divisional planes of the rock and lose altogether the font shape, as is wholly or partially the case under our larger waterfalls owing to the "pigmy plan" on which our (Slievardagh) rocks are broken up by planes. Fig. 2 will explain the meaning I wish to convey. Suppose the rocks broken by two sets of planes, and there may be many sets and the stratification as well; now suppose a font graven to the size of the circle; it is plain that this could not have stability, as the blocks at A, B, C, D would have come away during the process. But had the font been so small as to take only a portion of any four blocks no discontinuance of the graving action could yet have occurred.

I may add that about 2 feet in width and depth is the size of the largest font I have come upon hitherto.

WILLIAM MORRIS

Earlshill Colliery, Thurles

The Good Time Begun

THE following has just been received from a nephew in the Bombay Presidency, who, after speaking generally of a tremendous gale from the south-west, with heavy sea, fog, &c., all along the West Coast, writes thus more particularly:—

"That same mist and rain have been for the present the saving of this Presidency from another famine. It (the rain) has been general and heavy all over the country, and was just in time to save the crops, which were fast perishing from lack of moisture. If we have a little more this month and another good fall in September, we shall be quite safe; and I do trust we shall not be disappointed, as another year—the fourth in succession—of scarcity would well nigh make 'the bankruptcy of India,' so far as Bombay is concerned, a sad fact."

You will note the appearance of this desiderated Indian rain coming from the same direction as the chief part of that which has been deluging our own country; but which Mr. Campbell shrewdly attributed, in NATURE, vol. xx. p. 403, to the sun recovering his forces and beginning already to shine, after his recent languid, spotless years, with increased radiation on the great oceans of the south.

PIAZZI SMYTH

15, Royal Terrace, Edinburgh, August 30

Insect-Swarms

IN answer to Mr. Hawkshaw's question whether any one had seen a flight of moths and butterflies in England similar to the one he observed at Trouville on August 12 and 13, I can say that on August 12 I was walking on the Dawlish Warren (a bar of sand stretching across the mouth of the Exe) and noticed a great number of *P. gamma* moths; they were close to the edge of the water; many of them were dead, and the sand hoppers were eating them, but many more were alive and trying to flutter inland, but seemed too weak to do so. I picked up some and carried them to some wild thyme and they began to feed at once. Some of the moths were in good condition but others very much battered. The wind was blowing freshly from the sea at the time. The moths swarmed in the hedges all the way from our house to the Warren, a distance of four miles, especially on the bramble flowers. There were a great many *V. cardui* with the moths in the hedges, but none on the beach. A few days afterwards I had a letter from my brother at Dieppe saying there had been a swarm of moths and butterflies there, especially mentioning *P. gamma* and *V. cardui*, but there were also skippers and clouded whites. They swarmed about the town and country and were lying dead on the beach. The swarm of moths and butterflies was also on August 12.

EDITH PYCROFT

Kenton, near Exeter, August 31

Earthquake in Dominica

A SEVERE shock of earthquake was felt here at 1.20 A.M. yesterday (Sunday) the 10th instant, and at intervals, until 1.52, there were several tremulous movements of the earth. The noise immediately preceding the first shock reminded me of the clatter which is sometimes heard on board an ocean-going steamer in very rough weather, when a heavy sea strikes the ship, and all the crockery laid out for dinner is suddenly thrown from the "fiddles" and broken into pieces on the floor of the saloon.

After the first shock there was an interval of perfect quiet until 1.30, when subterranean noises like the discharging or booming of distant guns attracted my attention, and then, at

intervals varying from two to five minutes' duration, I counted six of these discharges, and following each discharge there came a gentle tremulous movement. Immediately after the last movement, heavy rain fell, and at 1.55 there were several flashes of very vivid lightning accompanied by loud peals of thunder. The rain continued to fall during all yesterday and last night.

Although Dominica is essentially of volcanic origin, and contains at the present day three active geysers, called respectively the Souffrière, the Walton Waven, and the Boiling Lake, no unusual quantity of sulphurous or mephitic vapours have lately been noticeable in the atmosphere; in fact, only one of the phenomena usually attending earthquakes preceded the shocks I have just described, and that was violent rain. The planters' "dry season" may be said to begin in January and to end in July, and during these months, harvesting, *i.e.*, sugar-making, goes on uninterruptedly. This year, however, there has been no "dry season," for 101·67 inches of rain have fallen on the east coast and 45·80 on the west coast of this island.

I may add, in conclusion, that being unwell and unable to sleep, I was reading by lamplight when the shocks above described took place, and that I timed them carefully with a chronometer-watch by Barraud and Lund, which was on a chair near my bed.

EDMUND WATT
Resident District Magistrate,
Leeward Islands

Dominica, British West Indies, August 11

Is it True that no Animal can be shown to have made Use of Antecedent Experience to intentionally improve upon the Past?

I HAD a pair of yellow African singing finches last year. The hen laid twenty-two eggs during the year, three at each nesting. In early spring I gave her materials to build with. She selected cotton wool and fine dryish grass for her purpose. It was very cold weather when she built her first nest in a little basket which I fixed high up in her cage.

The nest was a mere film of cotton wool lined with a few blades of grass. Of course the little creature could not sufficiently warm her eggs to hatch them, if they had proved fertile, which they did not.

At the end of fourteen days the cock, finding the eggs unhatched, set to work to bury them under cotton and grass (he being the only cock bird I had ever kept that built quite as well and as diligently as the hen did).

I then removed the eggs and the nest, and gave the birds fresh materials to build another nest with. They very soon accomplished this, making the nest of the same materials, *but thicker and more compact than the last.*

Again three white eggs were laid in it, but the hen could not get up the necessary degree of heat to hatch them, and at the end of fourteen days the cock set to work to build a third nest over them as before.

I again took away the nest and eggs, and I replaced the basket, this time covered externally with wadding and flannel, in hopes that thus I might help the hen to get up the proper temperature.

The little creatures immediately set to work to build again, but they this time built *a much thicker and warmer and more compact nest* than they had ever done before. The eggs proved fertile, and the process of incubation seemed to be successfully drawing to a close; but the patience of the cock did not suffice for the occasion. At the end of the tenth day he set to work to pull the cotton wool and grass about from the edges of the nest, and tried to bury the eggs as before, urging the hen to begin again also. This showed an unaccountable lack of instinct, not to say of reason; but surely the fact that the birds built each succeeding nest more and more thickly and warmly till incubation was possible indicates that they had made use of antecedent experience, and intentionally improved upon the past. These birds built a warm nest this spring, and succeeded in hatching a young one.

J. E. S.

Deltaic Growths

IN NATURE, vol. xix. p. 506, a Rangoon correspondent states that the Gulf of Martaban has shallowed 100 feet since the surveys of Captains Ross and Crawford, made probably thirty years ago. He is mistaken as to the date of these surveys for this reason:—

In 1822, at the outbreak of the first Burmese war, my father was appointed Flag Captain to Commodore Sir John Hayes's squadron, and he subsequently received the thanks of the Indian Government for, among other services, his surveys and explorations of the enemy's coasts and rivers. Now the soundings in the gulf would be about the first made. Hence the date would be 1822, or fifty-seven years ago. This shows an average annual deposit of 1·8 foot, which, although very much less than what Mr. Doyle imagines, is yet almost incredible. May there not have been a gradual rising of the sea bottom to assist?

FRASER S. CRAWFORD

Adelaide, South Australia, July 16

Sphinx (Deilephila) Lineata

As this insect is "unquestionably rare in England," and not common anywhere ("*D. Daucus*, a native of North America, being placed for it"—according to Mr. Stephens—"in collections"), perhaps I may be allowed to mention that a beautiful and perfect specimen of it was secured in my garden, on the 15th inst., by my little son, William Cecil. He was attracted to its resting-place in a wigelia bush by the flight there of a common gamma, and to his credit, inclosed it gently in his hand without the slightest injury—a prize indeed for a collector eight years old!

A specimen was also sent my daughter some months ago, from Porto Fino on the Riviera di Levante, by Mr. Robert Macdonald, but it was unfortunately wrecked in the post.

Bregner, Bournemouth, August 18 HENRY CECIL

The Recent Hail-storm

I INCLOSE a tracing of a broken window-pane—one of the the numerous cases of damage caused by the hail-storm on the morning of the 3rd inst. in this place. I almost fear the subject is one unworthy the attention of your readers, but I am curious to know what relation the space cut out may bear to the size of the hailstone causing it; and whether the clean and regular opening made would indicate an almost horizontal direction of the blow, as in the case of a bullet.

Observations of the extreme dimensions of the hailstones on that occasion are various among my neighbours, but one so large as 3½ inches seems incredible; and that one approaching such a size should strike a window at a right angle appears also improbable.

CHAS. FREDK. WHITE

42, Windsor Road, Ealing, August 20

OUR ASTRONOMICAL COLUMN

THE WASHINGTON CATALOGUE.—A second edition, as it is termed, of this extensive and useful work has been published, and will be found to be an even more important aid to the practical astronomer than the former one, which appeared as an appendix to the Washington volume for 1871, and to which reference has been made in this column as the "Washington General Catalogue." Like the first edition, it was prepared for publication by the late Prof. Yarnall, who died suddenly after a few hours' illness on February 27, having been an astronomer at the United States Naval Observatory for twenty-six years. In a note prefixed to this second edition, Admiral Rodgers, the present superintendent of the Observatory, handsomely acknowledges the extent and value of Prof. Yarnall's labours. A large majority of the observations upon which the catalogue is founded were made by him, as well as the computations, and the first printing of the work was executed under his immediate direction. It is stated that "the completed volume only reached him when he was already unconscious—an hour before his death. Astronomers will recognise in this volume not only a work of exceeding usefulness to them, but also a fitting memorial coming at the close of the long professional life of its author."

As was explained in the introduction to the former edition, the stars forming the catalogue consist mainly of stars used in observations with the zenith telescope, in the U.S. Army Surveys, in the lists of the Coast Survey, and many of Lacaille's stars mostly observed by Lacaille only. But there is a great addition of small stars, the

positions of which were required for the reduction of the observations made by the late Mr. James Ferguson during the years that he was so industriously and effectively observing with the equatorial. As a whole, therefore, the catalogue is a very miscellaneous one. The first edition contained 10,658 stars, with a number of cases, however, where the star had been observed only in one element, and included objects observed during the years 1845 to 1871. The new edition contains the results of observations to 1877, and includes 11,103 stars; the mean places are for the beginning of the year 1860, but it is to be borne in mind that they do not include any effect of proper motion from the mean date of observation, which is always given, to that general epoch. The annual precessions are annexed, without secular variation.

Like other publications of the U.S. National Observatory, the new Washington catalogue appears to have been most liberally circulated amongst astronomers.

NEW COMETS.—On August 21 a telescopic comet was discovered at Pola by Herr Palisa; its position at 10h. 26m. M.T. was in right ascension 150° 35′ and declination +49° 6′; daily motion in right ascension 1° 34′ increasing, and in declination 3 minutes diminishing; it was small but bright.

A second comet was discovered on August 24 at the Imperial Observatory, Strassburg, by Dr. Ernst Hartwig; it was then very faint and about $1\frac{1}{2}$ minutes in diameter. The following elements and ephemeris have been calculated by Dr. Hartwig, from the Strassburg observations on August 24 and 28, and one at Leipsic on August 26:—

Perihelion passage August 26·4661 M.T. at Berlin.

Longitude of perihelion	309° 56′·3	M.Eq. 1879·0.
,, ascending node ...	28 12·7	
Inclination	71 55·0	
Logarithm of perihelion distance	9·99056	

Motion—retrograde.

It will be found that these elements have no resemblance to those of any comet at present in our catalogues.

The following positions are for Berlin midnight:—

	Right Ascension. h. m. s.	Declination North. ° ′	Log. distance from Earth.	Sun.
Sept. 5	13 34 9	42 50·3	0·1055	9·9973
9	13 46 19	37 37·8	0·1314	0·0036
13	13 55 44	32 57·2	0·1577	0·0116
17	14 3 20	28 46·5	0·1834	0·0212
21	14 9 38	25 2·6	0·2081	0·0320
25	14 15 3	21 42·2	0·2315	0·0439
29	14 19 47	18 41·8	0·2535	0·0567

TO ASTRONOMERS

THE United States Naval Observatory will gratefully receive for its Library *separate copies* or *reprints* of memoirs published in the Transactions of learned societies or in journals. The volumes of Transactions are regularly received, but often many months after the reprints of particular papers, which are, therefore, especially valued.

It is also requested that all communications of this nature, and all correspondence relating to them, may be addressed to The Library, U.S. Naval Observatory, Washington, U.S.A.

Agents of the Smithsonian Institution abroad will receive large parcels for transmission. Smaller ones will be received more quickly if they are sent by post.

As far as possible the publications of the Observatory will be distributed to all working astronomers.

JOHN RODGERS,
Rear Admiral, U.S.N., Superintendent
Naval Observatory, Washington, D.C., August 18

GEOGRAPHICAL NOTES

THE Permanent Commission of the International Geodetic Association, presided over by General Ibañez, has decided to meet on the 16th inst. at Geneva, on the invitation which has been addressed to it by the Government of the little republic. The first official sitting is to be at 2 o'clock, on the 16th, at the Hotel de Ville of Geneva, in the room known as "the Alabama." In the evening Prof. E. Plantamour will hold a reception. The official sittings will continue daily at 10 A.M., in the same room, to the end of the week, interrupted on the 18th by a procession of steamers on the lake, which will occupy the whole of the day. On the evening of the 17th the Commissioners are invited to dine by the Council of the State of Geneva, and on the afternoon of the 19th there will be a reception at Sécheron by Prof. Plantamour. The programme of the session comprises: The reports of the Permanent Commission and the Central Bureau, the report of the Commission appointed at Hamburg in 1877 to consider the proposals of Lieut.-Col. Adan; the choice of the place of meeting of the sixth conference, and the appointment of special reporters to record the proceedings (1) As to determinations of latitude, longitude, and azimuth; (2) Triangulations and calculations of compensation of the networks; (3) Levelling operations and result of mareographic operations; (4) Measurements of the intensity of gravitation; (5) Publications relating to the measurement of degrees in Europe.

THE eminent African traveller, Dr. Junker, intends to start for Africa during this month. His first object is to reach Monbutta, which is to form the basis for his further investigations.

THE *Daily News* Lisbon correspondent telegraphs on September 2, that official news has arrived which states that on July 24 the explorers Ivens and Capello were in the district called Duque de Braganza. At the last session of the Geographical Society it was stated that the explorers were unable to continue their journey through want of means. The president promised to ask the Government to send them assitance. It will be remembered that Ivens and Capello started with Major Pinto.

WE find in the *Isvestia* of the Russian Geographical Society an interesting note by M. Potanin on the eastern Altai Mountains. Until 1869 these highlands were quite unknown, and even after the recent explorations of MM. Matusovsky and Sosnovsky it was considered that the Altai range did not go east of the meridian of Kobdo, where geographers, according to the map of Klaproth, supposed the existence of low hills which connected the Altai with the Tian Shan. Now M. Potanin proves that the Altai range goes further east, at least to the meridian of Lake Orok-nor, and that it is separated on its whole length by the Gobi steppe from the Tian Shan mountains. The altitude of the mountain passes in the parts visited by M. Potanin reaches as much as 8,000 feet. The eastern parts of the Altai mountains are rather dry, and forests in this part of the range are rather scarce.

THE same number of the *Isvestia* of the Russian Geographical Society contains an interesting note on the levelling accomplished during the last three years by the Russian General Staff on several lines of railways in Western Russia. The results are very satisfactory, as the probable error of this topographical levelling (with level and rule) does not exceed ± 2 inches on a distance of 100 versts (67 miles), *i.e.*, less than half the probable error of the best geodetical levellings. These levellings have brought to light a very interesting circumstance, namely, that the average level of the sea at Cronstadt is 13·2 ± 3·3 inches higher than at Dünamünde; the distance between the two towns being 240 miles. The Prussian levellings prove that the level of the Baltic is 20 inches higher at Kiel than at Memel.

CAPT. HOWGATE writes to us that he is preparing to send an expedition to the North Pole next year, independently of

the course to be taken by Congress next session. A ship fitted by him will start for Lady Franklin Bay, even if Congress leaves him unassisted.

NOTES

THE Central Meteorological Office of Italy (the Collegio Romano) has just issued the third part of a most useful series, forming one volume of 282 pp., imperial 8vo. (Imprimerie Héritiers Botta, Rome, 1879), which will be of great service to meteorologists generally. They contain a translation, in French, of all the Reports (*in extenso* or abridged) prepared upon the different questions comprised in the Programme of the Second International Meteorological Congress held at Rome in April of this year, together with many other papers communicated to the Congress. The work has been undertaken with the view of presenting to meteorologists, not only the whole of the questions which have been discussed by the Congress, but also the *ensemble* of the experiments and documents which have formed, so to speak, the basis of each discussion, and which represent, at the same time, the opinion ot the distinguished men from the whole of Europe upon the most important points of international meteorology. The translation has been carried out under the able superintendence of Prof. Guido Gras i, director of the Roman Central Office, and we congratulate that office upon the careful translation of the reports from the various languages and upon their speedy issue in one convenient volume.

OUR readers will be pleased to learn that Prof. Huxley's Introductory Primer to Macmillan's series of Science Primers will probably be published during the autumn; a considerable portion of it is already in type.

THE inauguration of Arago's statue will have the *éclat* of a national *fête*. The Municipal Council of Paris, of which Arago was an active member during Louis Philippe's reign, will send a deputation. The Bureau des Longitudes, the Observatory of Paris, and the Academy of Sciences, institutions which for years owed their lustre to the great Arago, are sending special representatives delegated for the purpose. M. Etienne Arago, the younger brother of the departed astronomer, a dramatic author, and M. Emmanuel Arago, his son, an influential member of the Senate, will be present at the ceremony, and will deliver addresses.

As will be seen from our British Association Reports, the Zoological Station at Naples has undertaken the publication of a new Zoological Record, in which equal attention will be paid to all departments of zoology. A large staff of zoologists of various nationalities will act as recorders, under the editorship of Prof. J. V. Carus, of Leipzig; and the first volume, dealing with the literature of the current year will appear in 1880. All those engaged in zoological work on any group of the animal kingdom are invited to send a copy of their papers to Prof. J. V. Carus, Leipzig, Querstrasse, 30; and to write on the address "for the Jahresbericht." Papers so sent will be distributed by Prof. Carus amongst the recorders, and after being abstracted for the Record, will be deposited in the library of the Zoological Station at Naples.

THE St. Petersburg Society of Naturalists has undertaken the publication of a complete Ornithology of Northern Russia. All who possess any data on that subject, or collections of birds, are requested to communicate them to "the St. Petersburg Society of Naturalists, at the University of St. Petersburg."

M. DOKUCHAIEFF, who was sent by the St. Petersburg Society of Naturalists for the exploration of the river and lacustrine quaternary deposits on the banks of the Oka, has discovered at the confluence of this river with the Frubesh, an immense quantity of stone implements. The dunes on the banks of the Oka in the neighbourhood of Kasimov town have also yielded a good many remains of prehistoric man. But the spot richest in remains is undoubtedly that five miles distant from Moorom town, where M. Dokuchaieff has found a remarkable variety of stone arrows, knives, and needles. As to the pieces, of wood which are very common in the blue clays of fluviolacustrine origin, and which were considered as remains of lacustrine dwellings, these are simply remains of forests which formerly covered all these deposits.

MR. CROOKES' admirable set of instruments for exhibiting the properties of radiant matter will be lectured upon at the Sorbonne at the beginning of next October, at the inauguration of the Autumn term of the Academy of Sciences.

ON October 6 next, a new Polytechnic Institution will be inaugurated at Hanover. The new building has recently been completed, and no cost has been spared to render it worthy to rank amongst the most complete and extensive buildings of the kind. Deputations from all the other polytechnic high school of Germany will participate in the inauguration-festivities.

THE death is announced of Dr. Otto Funke, Professor of Physiology at the University of Freiburg im Breisgau (Baden). Dr. Funke was an eminent physiologist, and lived at Leipzig for many years previous to his call to Freiburg. He died on August 16, at the age of fify-one years.

THE Congress of German Viticulturists is now meeting at Coblenz, and is discussing a number of viticultural questions of importance, including, of course, the much-ventilated phylloxera question. At the same place a meeting of Rhenish agriculturists will take place between September 7 and 10, accompanied by an agricultural exhibition.

THE Zoological Section of the Westphalian Provincial Society for Arts and Sciences had an interesting exhibition at the Zoological Gardens of Münster from August 17 to August 24 last. It consisted exclusively of invertebrate animals, illustrations of their habits and specimens of their products. The exhibition comprised insects (bees, beetles, butterflies, flies, grasshoppers, &c.), centipedes, spiders, crustaceans, annelids, molluscs (cephalopoda, gasteropoda, conchifera), echinoderms (holothuriæ, echinoidea, asteroidea), cœlenterata (medusæ), polyps, sponges, and infusoria. Most of the animals were represented in living as well as preserved specimens.

DURING the second week in August the German Anthropological Society met at Strasburg, under the presidency of Prof. Fraas. 164 members were present. Amongst the numerous interesting papers read we notice the following:—On the prehistoric map of Southern Germany and Eastern France, by Herr von Troeltsch; Professors Oehlenschlaeger (Munich) and Wagner (Karlsruhe) spoke on the same subject; Prof. Schaaffhausen (Bonn) lectured on skull measurements; Dr. Much (Vienna), on prehistoric traces of copper-mining; Prof. Klopfleisch (Jena), on his own excavations in Thuringia; a specially interesting papers was that by Herr Fischer (Freiburg), on the method of determining the age of stone weapons and utensils. Other papers were read by Dr. Gross (Naefels), on the pile-dwellings in the Biel Lake; Dr. Krause (Hamburg), on artificial alterations of the skulls of the natives of the New Hebrides; Dr. Mehlis (Tückheim), on the excavations at Limburg; Dr. Hook, on the stone age in Egypt. The next meeting of the Society will take place at Berlin, under the presidency of Prof. Virchow.

THE International Society for the prevention of the pollution of rivers, the soil, and the atmosphere, will hold its third meeting at Baden-Baden on the 16th and 17th inst.

AT Rome a new Society for furthering the introduction of cremation was formed on August 12 last. Many eminent medical men are members.

NEWS from the village of Havnen, Iceland, states that a violent volcanic eruption was observed at the end of May in the vicinity of the so-called Geisfugle shears, in the south-west of the island. It is curious that about the same time the eruption of Mount Etna took place.

THE first volume of a remarkable botanical work entitled "Versuch einer Entwickelungsgeschichte der Pflanzenwelt, insbesondere der Florengebiete seit der Tertiärperiode," by Dr. Ad. Engler, of Kiel, will be published next month by W. Engelmann, of Leipzig.

THE Rev. S. J. Whitmee informs us that he has received letters from the Society Islands assuring him there was no such devastation of the islands of Raiatea and Borabora (Porapora) by earthquake as was reported by Capt. Evers, and which is mentioned in the article "On Volcanic Phenomena during 1878," in NATURE, vol. xx. p. 378. No reference, he reminds us, is made in the article to the pumice and torn-up trees, carried apparently from the island of Birara, south-east to and beyond the Ellia Atolls, which he reported to us some months ago.

A CORRESPONDENT informs us that the observer of the Scottish Meteorological Society in Ireland reports fine weather there in June and July, with little or no rain, by which the pastures have suffered severely; but the fishing at most places is good, in direct contrast to what has prevailed in the British Isles.

THE City and Guilds Institute having granted 400*l.* per annum for purposes of technical education at University College, London, have resolved that the grant be appropriated in maintaining the chair of Chemical Technology, and that of Engineering and Mechanical Technology. The Professor of Chemical Technology, Dr. Charles Graham, has announced "Technical Education" as the subject of his public lecture at the College on October 1.

AN experiment before the Parisian press was tried on August 28, in the large room of the St. Lazare Railway Station, by a company started for establishing a Central Hall of Telephony under the Edison patent. The experiments were found quite satisfactory for musical instruments, but not so for the ordinary voice. The Company has received from the Government authority to inaugurate its operations, and a sum of 2*l.* per month is required for the use of a wire with the right of interchanging communications with any person having a wire directed to the Central Hall.

A SPECIAL excursion tour for members of the French Parliament has been organised to Algiers. The members will start in this month, and devote their vacation to the study of the land on behalf of which they are to legislate. The Municipal Council of Algiers has voted a sum of 200*l.* for the reception of their legislators.

WE take the following statements from a preliminary communication made to the Vienna Academy of Sciences by Herr G. L. Ciamician, with reference to the further results of his spectroscopic investigations:—"If the spectra of the metals of the alkaline earths are produced by the spark of an induction apparatus (with inserted Leyden jar) passing between the metals as electrodes in a hydrogen tube, then spectra are obtained which show the homology of the spectral lines in a most beautiful manner. The spectrum of magnesium, however, cannot be compared to the spectra thus obtained because it does not contain the less refrangible lines. If, however, the Leyden jar be removed, or if a weaker battery and a smaller induction coil be employed, all red and yellow lines in the spectra of calcium and strontium will disappear and spectra are obtained which are extremely similar to that of magnesium. If the less refrangible part of the spectrum of the group of alkaline earth-metals, which therefore is only visible at a high temperature (corresponding to a high electric tension), be compared to the less refrangible half of the complete oxygen spectrum, the remarkable similarity of these two spectrum-halves will at once strike the observer. The inference to be drawn from these facts would seem to be that the spectrum of the group of alkaline earth-metals is composed of the magnesium spectrum and of the less refrangible half of the oxygen spectrum.

A NUMBER of interesting observations made during a recent cruise of the French frigate *La Magicienne*, to various parts of the Pacific, chiefly formed the subject of a recent paper by Admiral Serres to the French Academy. Among other points attention had been drawn while at San Francisco to the swift tall-masted clipper ships which convey wheat to the European market. The modern practice of increasing the high sails at the expense of the lower is justified by science. During the voyage of *La Magicienne*, a Robinson anemometer was observed daily at an altitude of 8 metres, and twice every day the same instrument was observed at 36 metres. With very rare exceptions the velocity of the wind was always found much greater in the latter case than in the former. The average ratio deduced from thousands of observations was about 12 to 10. One can thus see the reason of seeking motive force in the upper regions.

PURSUING his researches on the scintillation of stars, M. Montigny shows, in a recent note to the Belgian Academy, that the following conclusion may be formulated:—When, in those observations where the colours characterising the phenomenon are distinctly separated, the blue tint predominates or is found in excess, rain may be expected, if it have not already come. There is great probability that the rain will be the more persistent and plentiful the more marked the predominance of blue. M. Montigny recalls the observations of P. Secchi, M. Janssen, and Prof. Piazzi Smyth, according to which the telluric lines of the solar spectrum increase in number and intensity in circumstances where the solar rays encounter a larger quantity of aqueous vapour in the atmosphere, either as the sun nears the horizon, or as the humidity of the air increases. Prof. Smyth bases predictions of rain on certain telluric bands in the spectrum, which he calls *rain-bands*. M. Montigny thinks there is no doubt that similar phenomena of absorption are produced in the case of certain rays emanating from the stars, where these traverse more or less moist layers of our atmosphere.

AN apparatus called the "telephone syren" has been recently described to the Schleswig-Holstein Society of Natural Sciences by Herr Karsten. On a circular disk 10 ctm. in diameter are fixed radially twenty-four small magnetic bars. This disk is rapidly rotated before a Bell telephone deprived of the iron plate. Where the same poles of the magnets are all directed outwards, one hears a certain tone; if the poles alternate, the lower octave is heard. If the succession of poles at the border of the disk be (say) N N S, there are heard three tones: one corresponding to the interval N N, one an octave lower corresponding to N S N, and a third combination-tone of three times the time of vibration of the highest, corresponding to the return, each time, of the first N. The vibration-numbers are thus as 3 : 2 : 1. Similar experiments may be made with the combination N N N S, where tones are obtained with the relation 4 : 2 : 1.

THE additions to the Zoological Society's Gardens during the past week include a Vervet Monkey (*Cercopithecus lalandii*) from South Africa, presented by Mr. W. T. Millar; a Rose Hill Parrakeet (*Platycercus eximius*) from New South Wales, presented by Mr. Arthur Stirling; a Common Kestrel (*Tinnunculus alaudarius*), British, presented by Mr. R. Moon; a Chequered Elaps (*Elaps lemniscatus*) from South America, presented by Dr. A. Stradling; an Annulated Snake (*Leptodira annulata*) from Colon, presented by Mr. R. F. Davis; three Horned Lizards

(*Phrynosoma cornutum*) from Texas, presented by Mr. Ernest E. Sabel; a Sulphur-breasted Toucan (*Ramphastos carinatus*) three Black-necked Stilt Plovers (*Himantopus nigricollis*), two Cayenne Lapwings (*Vanellus cayennensis*) from South America, a Slow Loris (*Nycticebus tardigradus*) from Malacca, a Radiated Tortoise (*Testudo radiata*) from Madagascar, two Electric Silurus (*Malapterurus beninensis*) from West Africa, purchased; a Squirrel-like Phalanger (*Belideus sciurea*), born in the Gardens.

ON RADIANT MATTER [1]

II.

Radiant Matter exerts strong Mechanical Action where it Strikes

WE have seen, from the sharpness of the molecular shadows, that radiant matter is arrested by solid matter placed in its path.

FIG. 10.

If this solid body is easily moved the impact of the molecules will reveal itself in strong mechanical action. Mr. Gimingham has constructed for me an ingenious piece of apparatus which when placed in the electric lantern will render this mechanical action visible to all present. It consists of a highly-exhausted glass tube (Fig. 11), having a little glass railway running along it from one end to the other. The axle of a small wheel revolves on the rails, the spokes of the wheel carrying wide mica paddles. At each end of the tube, and rather above the centre, is an aluminium pole, so that whichever pole is made negative the stream of radiant matter darts from it along the tube, and striking the upper vanes of the little paddle-wheel, causes it to turn round and travel along the railway. By reversing the poles I can arrest the wheel and send it the reverse way, and if I gently incline the tube the force of impact is observed to be sufficient even to drive the wheel up-hill.

This experiment therefore shows that the molecular stream

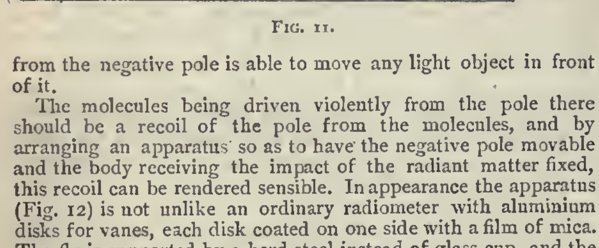

FIG. 11.

from the negative pole is able to move any light object in front of it.

The molecules being driven violently from the pole there should be a recoil of the pole from the molecules, and by arranging an apparatus so as to have the negative pole movable and the body receiving the impact of the radiant matter fixed, this recoil can be rendered sensible. In appearance the apparatus (Fig. 12) is not unlike an ordinary radiometer with aluminium disks for vanes, each disk coated on one side with a film of mica. The fly is supported by a hard steel instead of glass cup, and the needle-point on which it works is connected by means of a wire with a platinum terminal sealed into the glass. At the top of the radiometer bulb a second terminal is sealed in. The radiometer therefore can be connected with an induction-coil, the movable fly being made the negative pole.

For these mechanical effects the exhaustion need not be so high as when phosphorescence is produced. The best pressure for this electrical radiometer is a little beyond that at which the dark space round the negative pole extends to the sides of the glass bulb. When the pressure is only a few millims. of mercury, on passing the induction current a halo of velvety violet light forms on the metallic side of the vanes, the mica side remaining dark. As the pressure diminishes, a dark space is seen to separate the violet halo from the metal. At a pressure of half a millim. this dark space extends to the glass, and rotation commences. On continuing the exhaustion the dark space further widens out and appears to flatten itself against the glass, when the rotation becomes very rapid.

Here is another piece of apparatus (Fig. 13) which illustrates

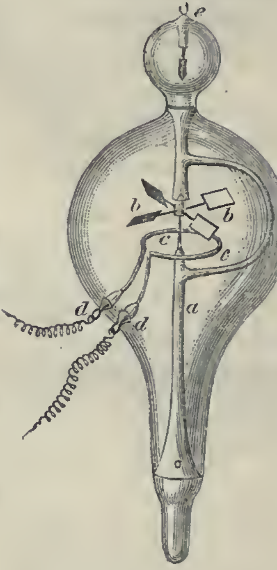

FIG. 12.

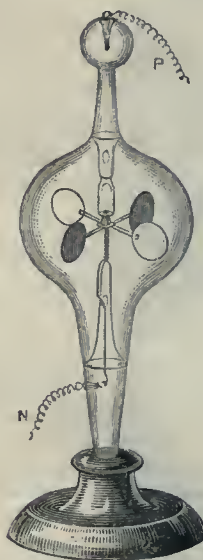

FIG. 13.

the mechanical force of the radiant matter from the negative pole. A stem (*a*) carries a needle-point in which revolves a light mica fly (*b b*). The fly consists of four square vanes of thin clear mica, supported on light aluminium arms, and in the centre is a small glass cap which rests on the needle-point. The vanes are inclined at an angle of 45° to the horizontal plane. Below the fly is a ring of fine platinum wire (*c c*), the ends of which pass through the glass at *d d*. An aluminium terminal (*e*) is sealed in at the top of the tube, and the whole is exhausted to a very high point.

By means of the electric lantern I project an image of the vanes on the screen. Wires from the induction-coil are attached,

FIG. 14.

so that the platinum ring is made the negative pole, the aluminium wire (*e*) being positive. Instantly, owing to the projection of radiant matter from the platinum ring, the vanes rotate with extreme velocity. Thus far the apparatus has shown nothing more than the previous experiments have prepared us to expect; but observe what now happens. I disconnect the induction-coil altogether, and connect the two ends of the platinum wire with a small galvanic battery; this makes the ring *c c* red-hot, and under this influence you see that the vanes spin as fast as they did when the induction-coil was at work.

Here, then, is another most important fact. Radiant matter in these high vacua is not only excited by the negative pole of an induction-coil, but a hot wire will set it in motion with force sufficient to drive round the sloping vanes.

[1] A lecture delivered to the British Association for the Advancement of Science, at Sheffield, Friday, August 22, 1879, by William Crookes, F.R.S. Continued from p. 423.

Radiant Matter is deflected by a Magnet

I now pass to another property of radiant matter. This long glass tube (Fig. 14), is very highly exhausted; it has a negative pole at one end (*a*) and a long phosphorescent screen (*b, c*) down the centre of the tube. In front of the negative pole is a plate of mica (*b, d*) with a hole (*e*) in it, and the result is, when I turn on the current, a line of phosphorescent light (*e, f*) is projected along the whole length of the tube. I now place beneath the tube a powerful horse-shoe magnet: observe how the line of light (*e, g*) becomes curved under the magnetic influence waving about like a flexible wand as I move the magnet to and fro.

This action of the magnet is very curious, and if carefully followed up will elucidate other properties of radiant matter. Here (Fig. 15) is an exactly similar tube, but having at one end a small potash tube, which if heated will slightly injure the vacuum. I turn on the induction current, and you see the ray of radiant matter tracing its trajectory in a curved line along the screen, under the influence of the horse-shoe magnet beneath. Observe the shape of the curve. The molecules shot from the negative pole may be likened to a discharge of iron bullets from a mitrailleuse, and the magnet beneath will represent the earth curving the trajectory of the shot by gravitation. Here on this luminous screen you see the curved trajectory of the shot accurately traced. Now suppose the deflecting force to remain constant, the curve traced by the projectile varies with the velocity. If I put more powder in the gun the velocity will be greater and the trajectory flatter, and if I interpose a denser resisting medium between the gun and the target, I diminish the velocity of the shot, and thereby cause it to move in a greater curve and come to the ground sooner. I cannot well increase before you the velocity of my stream of radiant molecules by putting more

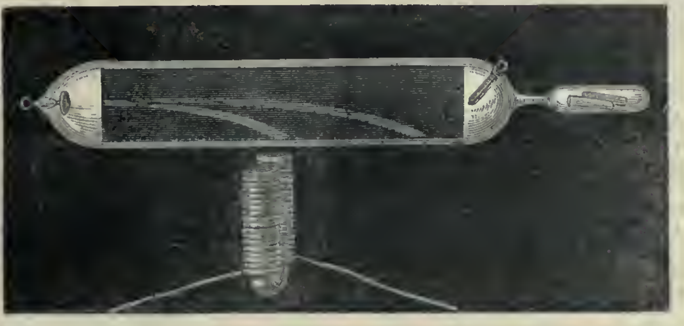

FIG. 15.

powder in my battery, but I will try and make them suffer greater resistance in their flight from one end of the tube to the other. I heat the caustic potash with a spirit-lamp and so throw in a trace more gas. Instantly the stream of radiant matter responds. Its velocity is impeded, the magnetism has longer time on which to act on the individual molecules, the trajectory gets more and more curved, until, instead of shooting nearly to the end of the tube, my molecular bullets fall to the bottom before they have got more than half-way.

It is of great interest to ascertain whether the law governing the magnetic deflection of the trajectory of radiant matter is the same as has been found to hold good at a lower vacuum. The experiments I have just shown you were with a very high vacuum. Here is a tube with a low vacuum (Fig. 16). When I turn on the induction spark, it passes as a narrow line of violet light

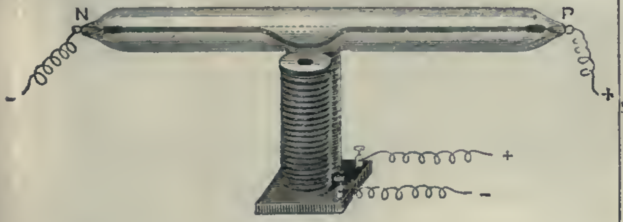

FIG. 16.

joining the two poles. Underneath I have a powerful electromagnet. I make contact with the magnet, and the line of light dips in the centre towards the magnet. I reverse the poles, and the line is driven up to the top of the tube. Notice the difference between the two phenomena. Here the action is temporary. The dip takes place under the magnetic influence; the line of discharge then rises and pursues its path to the positive pole. In the high exhaustion, however, after the stream of radiant matter had dipped to the magnet, it did not recover itself, but continued its path in the altered direction.

By means of this little wheel, skilfully constructed by Mr. Gimingham, I am able to show the magnetic deflection in the electric lantern. The apparatus is shown in this diagram (Fig. 17). The negative pole (*a, b*) is in the form of a very shallow cup. In front of the cup is a mica screen (*c, d*), wide enough to intercept the radiant matter coming from the negative pole. Behind this screen is a mica wheel (*e, f*) with a series of vanes, making a sort of paddle-wheel. So arranged, the molecular rays from the pole *a b* will be cut off from the wheel, and will not produce any movement. I now put a magnet, *g*, over the tube, so as to deflect the stream over or under the obstacle *c, d*, and the result will be rapid motion in one or the other direction, according to the way the magnet is turned. I throw the image of the apparatus on the screen. The spiral lines painted on the wheel show which way it turns. I arrange the magnet to draw the molecular stream so as to beat against the upper vanes, and the wheel revolves rapidly as if it were an overshot water-wheel. I turn the magnet so as to drive the radiant

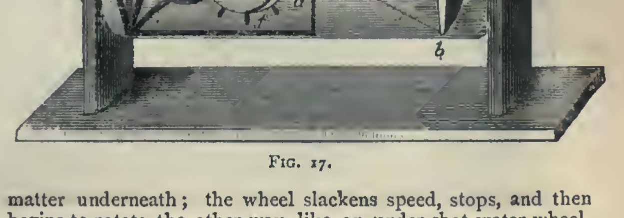

FIG. 17.

matter underneath; the wheel slackens speed, stops, and then begins to rotate the other way, like an under-shot water-wheel. This can be repeated as often as I reverse the position of the magnet.

I have mentioned that the molecules of the radiant matter discharged from the negative pole are negatively electrified. It is probable that their velocity is owing to the mutual repulsion between the similarly electrified pole and the molecules. In less high vacua, such as you saw a few minutes ago (Fig. 16), the discharge passes from one pole to another, carrying an electric current, as if it were a flexible wire. Now it is of great interest

to ascertain if the stream of radiant matter from the negative pole also carries a current. Here (Fig. 18) is an apparatus which will decide the question at once. The tube contains two negative terminals (*a*, *b*) close together at one end, and one positive terminal (*c*) at the other. This enables me to send two streams of radiant matter side by side along the phosphorescent screen—or by disconnecting one negative pole, only one stream.

If the streams of radiant matter carry an electric current they will act like two parallel conducting wires and attract one

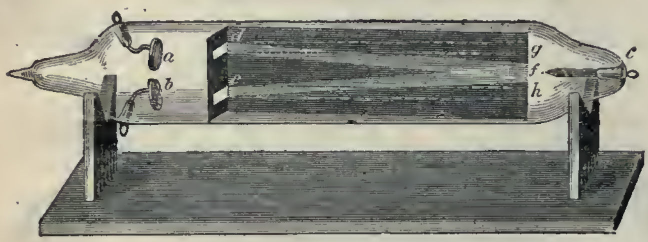

Fig. 18.

another; but if they are simply built up of negatively electrified molecules they will repel each other.

I will first connect the upper negative pole (*a*) with the coil, and you see the ray shooting along the line *d*, *f*. I now bring the lower negative pole (*b*) into play, and another line (*e*, *h*) darts along the screen. But notice the way the first line behaves; it jumps up from its first position, *d f*, to *d g*, showing that it is repelled, and if time permitted I could show you that the lower ray is also deflected from its normal direction: therefore the two parallel streams of radiant matter exert mutual repulsion, acting not like current carriers, but merely as similarly electrified bodies.

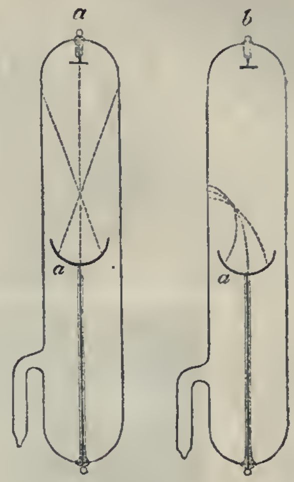

Fig. 19.

Radiant Matter produces Heat when its Motion is arrested

During these experiments another property of radiant matter has made itself evident, although I have not yet drawn attention

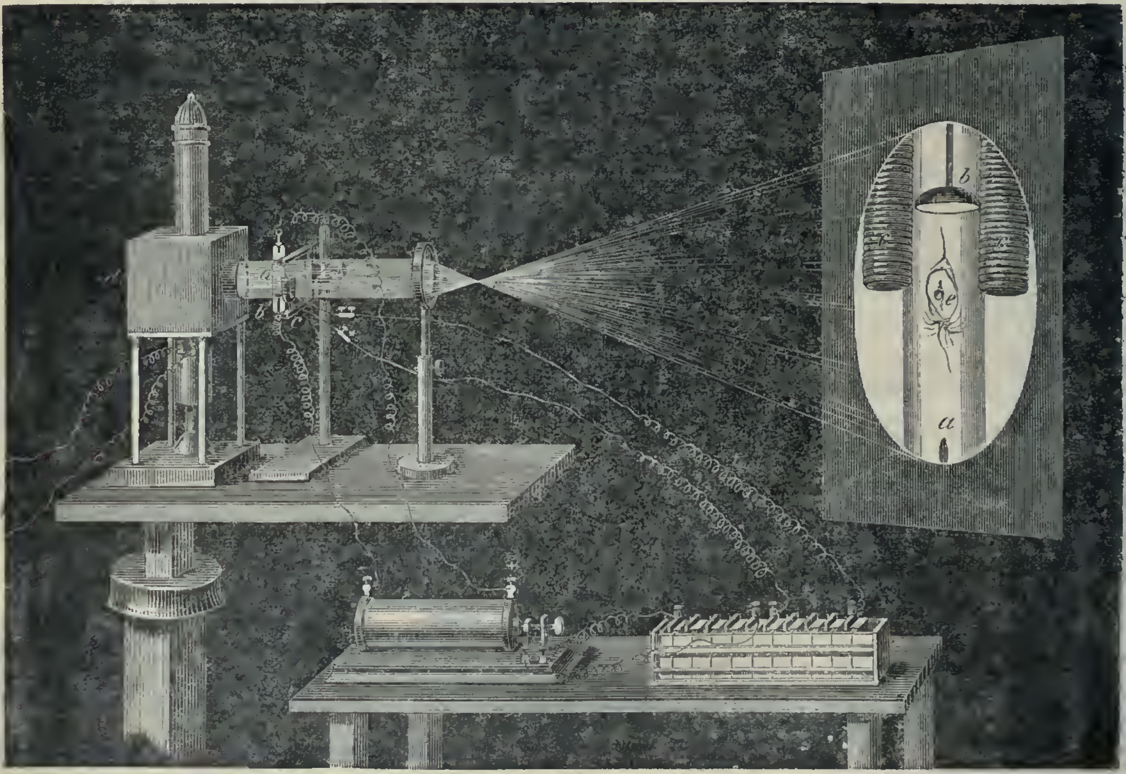

Fig. 20.

to it. The glass gets very warm where the green phosphorescence is strongest. The molecular focus on the tube, which we saw earlier in the evening (Fig. 8) is intensely hot, and I have prepared an apparatus by which this heat at the focus can be rendered apparent to all present.

I have here a small tube (Fig. 19, *a*) with a cup-shaped negative pole. This cup projects the rays to a focus in the middle of the tube. At the side of the tube is a small electro-magnet, which I can set in action by touching a key, and the focus is then drawn to the side of the glass tube (Fig. 19, *b*). To show the first action of the heat I have coated the tube with wax. I will put the apparatus in front of the electric lantern (Fig. 20, *d*), and throw a magnified image of the tube on the screen. The coil is now at work, and the focus of molecular

rays is projected along the tube. I turn the magnetism on, and draw the focus to the side of the glass. The first thing you see is a small circular patch melted in the coating of wax. The glass soon begins to disintegrate, and cracks are shooting star-wise from the centre of heat. The glass is softening. Now the atmospheric pressure forces it in, and now it melts. A hole (*e*) is perforated in the middle, the air rushes in, and the experiment is at an end.

I can render this focal heat more evident if I allow it to play on a piece of metal. The bulb (Fig. 21) is furnished with a negative pole in the form of a cup (*a*). The rays will therefore be projected to a focus on a piece of iridio-platinum (*b*) supported in the centre of the bulb.

I first turn on the induction-coil slightly, so as not to bring out its full power. The focus is now playing on the metal, raising it to a white heat. I bring a small magnet near, and you see I can deflect the focus of heat just as I did the luminous focus in the other tube. By shifting the magnet I can drive the focus up and down, or draw it completely away from the metal, and leave it non-luminous. I withdraw the magnet, and let the molecules have full play again; the metal is now white hot. I increase

Fig. 21.

the intensity of the spark. The iridio-platinum glows with almost insupportable brilliancy, and at last melts.

The Chemistry of Radiant Matter

As might be expected, the chemical distinctions between one kind of radiant matter and another at these high exhaustions are difficult to recognise. The physical properties I have been elucidating seem to be common to all matter at this low density. Whether the gas originally under experiment be hydrogen, carbonic acid, or atmospheric air, the phenomena of phosphorescence, shadows, magnetic deflection, &c., are identical, only they commence at different pressures. Other facts, however, show that at this low density the molecules retain their chemical characteristics. Thus by introducing into the tubes appropriate absorbents of residual gas, I can see that chemical attraction goes on long after the attenuation has reached the best stage for showing the phenomena now under illustration, and I am able by this means to carry the exhaustion to much higher degrees that I can get by mere pumping. Working with aqueous vapour I can use phosphoric anhydride as an absorbent; with carbonic acid, potash; with hydrogen, palladium; and with oxygen, carbon, and then potash. The highest vacuum I have yet succeeded in obtaining has been the 1-20,000,000th of an atmosphere, a degree which may be better understood if I say that it corresponds to about the hundredth of an inch in a barometric column three miles high.

It may be objected that it is hardly consistent to attach primary importance to the presence of *Matter*, when I have taken extraordinary pains to remove as much matter as possible from these bulbs and these tubes, and have succeeded so far as to leave only about the one-millionth of an atmosphere in them. At its ordinary pressure the atmosphere is not very dense, and its recognition as a constituent of the world of matter is quite a modern notion. It would seem that when divided by a million, so little matter will necessarily be left that we may justifiably neglect the trifling residue and apply the term *vacuum* to space from which the air has been so nearly removed. To do so, however, would be a great error, attributable to our limited faculties being unable to grasp high numbers. It is generally taken for granted that when a number is divided by a million the quotient must necessarily be small, whereas it may happen that the original number is so large that its division by a million seems to make little impression on it. According to the best authorities, a bulb of the size of the one before you (13·5 centimetres in diameter) contains more than 1,000,000,000,000,000,000,000,000 (a quadrillion) molecules. Now, when exhausted to a millionth of an atmosphere we shall still have a trillion molecules left in the bulb—a number quite sufficient to justify me in speaking of the residue as *matter*.

To suggest some idea of this vast number I take the exhausted bulb, and perforate it by a spark from the induction-coil. The spark produces a hole of microscopical fineness, yet sufficient to allow molecules to penetrate and to destroy the vacuum. The inrush of air impinges against the vanes, and sets them rotating after the manner of a windmill. Let us suppose the molecules to be of such a size that at every second of time a hundred millions could enter. How long, think you, would it take for this small vessel to get full of air? An hour? A day? A year? A century? Nay, almost an eternity! A time so enormous that imagination itself cannot grasp the reality. Supposing this exhausted glass bulb, indued with indestructibility, had been pierced at the birth of the solar system; supposing it to have been present when the earth was without form and void; supposing it to have borne witness to all the stupendous changes evolved during the full cycles of geologic time, to have seen the first living creature appear, and the last man disappear; supposing it to survive until the fulfilment of the mathematician's prediction that the sun, the source of energy, four million centuries from its formation, will ultimately become a burnt-out cinder;[1] supposing all this—at the rate of filling I have just described, 100 million molecules a second—this little bulb even then would scarcely have admitted its full quadrillion of molecules.[2]

But what will you say if I tell you that all these molecules, this quadrillion of molecules, will enter through the microscopic hole before you leave this room? The hole being unaltered in size, the number of molecules undiminished, this apparent paradox can only be explained by again supposing the size of the molecules to be diminished almost infinitely—so that instead of entering at the rate of 100 millions every second, they troop in at a rate of something like 300 trillions a second. I have done the sum, but figures when they mount so high cease to have any meaning, and such calculations are as futile as trying to count the drops in the ocean.

In studying this fourth state of matter we seem at length to have within our grasp and obedient to our control the little indivisible particles which with good warrant are supposed to constitute the physical basis of the universe. We have seen that in some of its properties radiant matter is as material as this table, whilst in other properties it almost assumes the character of radiant energy. We have actually touched the borderland where matter and force seem to merge into one another, the shadowy realm between Known and Unknown which for me has always

[1] The possible duration of the sun from formation to extinction has been variously estimated by different authorities, at from 18 million years to 400 million years. For the purpose of this illustration I have taken the highest estimate.

[2] According to Mr. Johnstone Stoney (*Phil. Mag.*, vol. 36, p. 141), 1 c.c. of air contains about 1,000,000,000,000,000,000,000 molecules. Therefore a bulb 13·5 centims. diameter contains $13{\cdot}5^3 \times 0{\cdot}5236 \times$ 1,000,000,000,000,000,000,000 or 1,288,252,350,000,000,000,000,000 molecules of air at the ordinary pressure. Therefore the bulb when exhausted to the millionth of an atmosphere, contains 1,288,252,350,000,000,000 molecules, leaving 1,288,251,061,747,650,000,000,000 molecules to enter through the perforation. At the rate of 100,000,000 molecules a second, the time required for them all to enter will be

12,882,510,617,476,500 seconds, or
214,708,510,291,275 minutes, or
3,578,475,171,521 hours, or
149,103,132,147 days, or
408,501,731 years.

had peculiar temptations. I venture to think that the greatest scientific problems of the future will find their solution in this Border Land, and even beyond; here, it seems to me, lie Ultimate Realities, subtle, far-reaching, wonderful.

"Yet all these were, when no Man did them know,
Yet have from wisest Ages hidden beene;
And later Times thinges more unknowne shall show.
Why then should witlesse Man so much misweene,
That nothing is, but that which he hath seene?"

THE BRITISH ASSOCIATION

GENERAL satisfaction is expressed with the Sheffield meeting. The people of the town and district did their best, amid many difficulties, to give the members of the Association a hearty reception, and they succeeded. The excursions on Thursday were well attended, and those who took part in them seem to have enjoyed themselves. At the meeting of the General Committee, Swansea was selected as next year's place of meeting, with Prof. A. R. Ramsay as president; the date of meeting is August 25. A letter was read from the Archbishop of York, warmly urging upon the Association to meet in the archiepiscopal City in 1881, when, for some unaccountable reason, the jubilee is to be celebrated, as we have already said, in the fifty-first year of the Association's existence. As the result of the important discussion in Section F on science teaching in schools, a committee was appointed for the purpose of reporting, in addition to other matters, whether it is important that her Majesty's inspectors of elementary schools should be appointed with reference to their ability for examining on scientific specific subjects of the code, the committee to consist of Mr. Mundella, M.P., Mr. Shaw, Mr. Bourne, Mr. Jas. Heywood, Mr. Wilkinson, and Dr. J. H. Gladstone.

REPORTS

Report of the Committee on Erratic Blocks, presented by the Rev. H. W. Crosskey, F.G.S. (Abstract.)

Several contributions of interest and importance have been received respecting the position and distribution of erratic blocks.

A granite boulder 3 × 2·5 × 2 feet has been found by Mr. Hall, in the village of Bickington, parish of Fremington. There is no similar rock nearer than Lundy Island, twenty-five miles west-north-west from the boulder and Dartmoor, twenty-five miles south by east. Its height above the sea is 80 feet.

Among the most remarkable erratic blocks yet described in the midland district, are those reported upon Frankley Hill, at a height of 650 feet above the sea. They were examined by the writer in company with Prof. T. G. Bonney, and the following is a summary of the observations made:—

A section of drift beds is exposed in a cutting of the new Hales Owen Railway passing through Frankley Hill. The section is as follows:—Permian clay, sand of clayey texture, yellowish sand, greyish sandy clay with brinter pebbly clay, somewhat sandy. The heights of the clays and sands are very irregular throughout the section which is in itself about 60 feet in depth.

Fragments of permian sandstone (which is exposed in a part of the section) are scattered through the sands and clays, but erratic blocks are rare. Indeed, one only—a green-stone—was noticed in the cutting itself, although others doubtless occur.

No part of this section can be called a "boulder clay"—if by "boulder clay" be meant either a clay formed beneath land ice, or a clay carried away by an iceberg and deposited on the sea-bottom, as the berg melted or stranded.

The various sands and gravels have all the appearance of being a "wash" from older beds, effected during the depression and subsequent upheaval of the present land surface. They are neither compactly crowded with erratics, nor are fragments of local rocks heaped irregularly together, and grooved and striated. The way in which the pieces of native rock are scattered through the beds, does not indicate any other force than that which would be exerted by the ordinary "wash" of the waters during the movements just mentioned.

The presence of a few erratics shows that the *wash* must have taken place beneath the waters of a glacial sea, over which icebergs floated.

These beds appear to have been formed in the earlier rather than the later part of the glacial epoch. In a field *on the summit of the section* a large number of erratics are to be seen which have been taken from a recent surface-drain. Twenty of these boulders are felsite, two are basalt, one is a piece of vein-quartz, and one is a Welsh diabase. They constitute a group of allied rocks, evidently from one district. Probably they belong to the great Arenig dispersion. Two of the felsites close to the group are of considerable size, the larger being about 6 × 4 × 2 feet. Similar blocks may be traced to the summit of the hill. One felsite boulder opposite the Yew Trees is about 4·5 × 3 × 2 feet, and is partly buried in the ground.

The height of the boulders above the sea is remarkable, their highest level being 650 feet.

This indicates a corresponding depression of the land, since no Welsh glacier could have travelled over hill and down dale to this summit-level. To render any such glacier work conceivable, the Welsh mountains must have stood at a height beyond any point for which there is the slightest evidence.

This group of boulders on Frankley Hill appears to have been dropped by an iceberg travelling from Wales upon the top of the clays and sands exposed in the railway cutting at a time when the land was depressed at least 700 feet. In the clays and sands upon which the summit group of erratics rests, we must have beds belonging to an earlier date than the *close* of the glacial epoch; and the erratics in the cutting must be discriminated from those left at the higher level.

Some remarkable boulders were described from the neighbourhood of Wolverhampton: (1) a striated boulder of felsite 11 × 3 × 3 feet; (2) one of slate, broken into two parts, but which, when whole, measured 11·25 × 6·25 × 3·5 feet; (3) one of granite about 4·75 feet in each dimension, and weighing about three tons.

Mr. D. Mackintosh traces the origin of the so-called "greenstone" boulders (more properly to be called diorites or dolerites) around the estuaries of the Mersey and the Dee.

The area in which they are very much concentrated is intensely striated, and nearly all the striæ point divergently to the south of Scotland, *i.e.*, between N. 15° W. and N. 45° W.

A large "greenstone" boulder has been found at Crosby, resting on a perfectly flat glaciated rock surface, with striæ pointing N. 40° W.

Additional presumptions in favour of the Scottish derivation of these boulders may be found (1) in the fact that nearly all these boulders consist of basic rocks similar to some found in the south of Scotland, and (2) in the extent to which they are locally concentrated on the peninsula of Wirral and the neighbouring part of Lancashire. Many fresh greenstone boulders have been lately exposed in the newest Bootle Dock excavation. The largest is 6 × 4·5 × 3 feet, and was found on the surface of the upper boulder clay. As a rule these boulders are excessively flattened and regularly grooved.

Mr. J. R. Dakyns describes the occurrence of Shap granite boulders on the Yorkshire coast. There are several at Long Nab on the north side of the Nab; one of these measures 3 cubic feet. Others are on the north side of Cromer Point; south of Cromer Point there are more till you come nearly to Filey. There is one measuring 3 × 2·5 × 2 feet on the top of the cliff about a mile from Filey. It is probably practically undisturbed, for the ground slopes inland from the cliff, and therefore, if it has been turned up in ploughing and moved, it cannot have been moved far, for no one would take the trouble to cart a huge boulder far up-hill.

There are several boulders of Shap granite on the shore along the north of Filey Bay, but none along the south till one reaches Flamborough Head. Several occur along the shore between Flamborough Head and Flamborough south landing; one of these measures 36 cubic feet. One may be seen rather more than a mile south of Bridlington Quay, and doubtless they have travelled still further south, since there is one built into a wall at Hornsea.

The destruction of erratic blocks is going on so rapidly that the Committee invite continued contributions of information concerning them.

Report of the "Geological Record" Committee, by W. Whitaker, B.A., F.G.S.—Since the last meeting of the Association the third volume of the "Geological Record" has been published. This gives an account of books, papers, &c., on geology, mineralogy, and palæontology published at home and abroad during the year 1876. The fourth volume (for 1877) is in the

press; and part of the MS. for the fifth volume (for 1878) is in hand. The average size of the three published volumes is 440 pages, each volume recording over 2,000 papers, &c.

Fifteenth Report of the Committee for Exploring Kent's Cavern, Devonshire. Drawn up by W. Pengelly, F.R.S.—Work during the past year has been carried on in the "High Chamber" and its branches. This chamber extends for about 53 feet in a north-westerly direction from the "Cave of Inscriptions." At its inner or north-western end it sends off two branches; the northern branch was excavated for about 12 feet, when the work was abandoned, as breccia, blocks of limestone, and crystalline stalagmite reached the roof and rendered further progress difficult and expensive. The "High Chamber" contains only breccia, the oldest mechanical deposit in the cavern, and the crystalline stalagmite which overlies it. Bones of bears and implements have been found in the breccia here, and some recent objects were found on or near the surface. The southern branch of the High Chamber is called the "Swallow Gallery," from a swallow-hole which occurs about 18 feet from the entrance. This has been explored for about 50 feet. It also contains only breccia, generally lying bare, but covered with crystalline stalagmite at the inner part of the chamber. Here too the remains consist chiefly of bear; a few implements have also been found. There were entrances to the cavern by the Swallow Gallery and through the swallow holes; but these were quite closed before the beginning of the "cave-earth era," and have since remained so. Excavations have also been made in Clinnick's Gallery; but here, as in former years, the number of "finds" has been small.

Prof. A. Leith Adams has availed himself of the collection of mammoth remains made during several years from Kent's Cavern, to illustrate his memoir for the Palæontological Society on "British Fossil Elephants." Extracts from this memoir are given in the report, and especial mention is made of a molar found in 1874 in the "Cave of Rodentia." Prof. Adams says:—"This tooth is one of the smallest milk-molars of any elephant with which I am acquainted, and is even more diminutive than the first milk-teeth of the Maltese pigmy elephants."

Report on the Miocene Flora, &c., of the North of Ireland, by W. H. Baily.—The plants occur, between two beds of basalt, in a deposit of brown and red bole, and immediately overlying a bed of pisolitic iron ore, which has been extensively worked. Twenty-five species of plants have been determined; they are most closely allied to the fossil flora of North Greenland, some of the forms also occurring at Bovey Tracy.

Sixth Report of a Committee consisting of Professors Herschel and Lebour, and Mr. J. T. Dunn, to determine the Thermal Conductivities of certain Rocks, showing especially the Geological Aspects of the Investigation.—The research and correspondence which it would require to complete a historical sketch of the attempts already made to determine by experiments the thermal conductivities of the most widely distributed terrestrial rocks, which the Committee proposed to prepare during the past year, are not so far advanced at present as to allow them to be comprehended in this year's Report. But the Committee hopes during the coming year by continuing its inquiries with the addition to its numbers of the names of Professors W. E. Ayrton and J. Perry, of the Imperial College of Engineering in Japan, to carry out the object of its undertaking, so as to exhibit the state of our knowledge of the data of thermal conductivity of those widespread kinds of rock which constitute the external materials of the globe.

The Committee has obtained during the past year some measurements of thermal conductivities both of rocks and ebonite, and india-rubber, and corroborates the very low value found by Prof. Stefan, of Vienna, for the conductivity of ebonite. It has also corrected some imperfections of its former tables, by showing that the values given in them have throughout been described too low, by about an eighth of their assigned values, and find that with this correction their results have been in close accordance with the measures that Sir William Thomson and other observers deduced of the conductivities of soils and rocks in places where underground thermometers have been sunk and read regularly for many years. The records of such thermometers in the grounds of the Royal Observatory at Greenwich have been preserved continuously for more than thirty years, and the last volume of "Greenwich Meteorological Reductions" contains the observations of their temperatures for twenty-seven successive years, 1847-73. This record (already used in part by Prof. Everett) might now afford a new and very valuable determination of the conductivity of sand and gravel strata, such as make up the materials of Greenwich Hill, upon which the Royal Observatory is placed.

Report of the Committee, consisting of Prof. Sir William Thomson, Prof. Clerk-Maxwell, Prof. Tait, Dr. C. W. Siemens, Mr. F. J. Bramwell, and Mr. J. T. Bottomley for commencing Secular Experiments upon the Elasticity of Wires, by J. T. Bottomley.—At the last meeting of the British Association, the arrangements for suspending wires for secular experiments in the tube which has been erected in the tower of the Glasgow University Buildings, and for observing these wires, were described and reported as complete. Some improvements have since been found necessary; but, so far as these are concerned, there is not much to add to the report then given.

The long iron tube has been closed at the top and bottom so as to keep out currents of air and dust, and the joints of the tube have been carefully caulked.

Some improvements in the cathetometer used for observing the marks on the wires were also found to be required, but the instrument is now satisfactory.

Six wires have now been suspended in the tube; their stretching weights have been attached to them, and they have been carefully marked and measured. These wires are suspended in pairs—two of gold, two of platinum, and two of palladium. One of each of the pairs is loaded with a weight equal to one-twentieth of its breaking weight, and the other of each pair with a weight equal to one-half of its breaking weight. The points of suspension for each pair are very close together, so that any yielding of the place of support affects both wires equally.

Each wire is marked with paint marks, and there are other marks on the wires and on the weights attached to them where positions have been determined. These marks are described in a laboratory book which is at present kept in the room of the professor of natural philosophy in the University of Glasgow. The measurements that have been made, and the experiments that have been undertaken in connection with the work assigned to the Committee, are all being entered in this book. This, however, can only be regarded as a temporary mode of keeping these records.

It is intended that the record in this book shall contain—

1. Description of the tube and arrangements for suspending the wires, and for suspending additional wires at future times, and description of the mode of attachment of the stretching weights.

2. Description of the cathetometer and method of measuring the changes, should there be any, in the lengths of the wires.

3. Description of the wires themselves, and record of experiments that have already been made on them as to breaking weight and Young's modulus of elasticity.

4. Description of the marks put on the wires, and record of the measurements that have been made as to the lengths of the wires and as to the relative positions of the marks at the time of suspending the wires.

The stretching weight and the clamps attached to the wires are engraved each with the amount of its weight in grammes. The measurements are all made in grammes and centimetres.

It seems desirable, considering the nature of the experiments that are just now commencing, that information regarding them should be preserved to the British Association in some appropriate way; and that provision should be made for recording every change that may take place, and for communicating from time to time to the Association such information as may be obtained.

In the report presented to the Association by this Committee last year, it was mentioned that experiments had been commenced in the laboratory of the University of Glasgow in connection with the present investigation on the effects of stress maintained for a considerable time in altering the elastic properties of various wires. These experiments are still being carried on, and results of interest and importance have been already arrived at.

The most important of these experiments form a series that have been made on the elastic properties of very soft iron wire. The wire used was drawn for the purpose, and is extremely soft and very uniform. It is about No. 20 B.W.G., and its breaking weight, tested in the ordinary way, is about 45 lbs. This wire has been hung up in lengths of about 20 feet, and broken by weights applied, the breaking being performed more or less slowly.

In the first place, some experiments have been tried as to the smallest weight which, applied very cautiously and with precautions against letting the weight run down with sensible velocity, will break the wire. These experiments have not yet been very satisfactorily carried out, but it is intended to complete them.

The other experiments have been carried out in the following way:—It was found that a weight of 28 lbs. does not give permanent elongation to the wire taken as it was supplied by the wire drawer. Each length of the wire, therefore, as soon as it was hung up for experiment, was weighted with 28 lbs., and this weight was left hanging on the wire for 24 hours. Weights were then added till the wire broke, measurements as to elongation being taken at the same time. A large number of wires were broken with equal additions of weight, a pound at a time, at intervals of from three to five minutes—care being taken in all cases, however, not to add fresh weight if the wire could be seen to be running down under the effect of the weight last added. Some were broken with weights added at the rate of one pound per day, some with three-quarters of a pound per day, and some with half a pound per day. One experiment was commenced in which it was intended to break the wire at a very much slower rate than any of these. It was carried on for some months, but the wire unfortunately rusted, and broke at a place which was seen to be very much eaten away by rust, and with a very low breaking weight. A fresh wire has been suspended, and is now being tested. It has been painted with oil, and has now been under experiment for several months.

The following tables will show the general results of these experiments. It will be seen, in the first place, that the prolonged application of stress has a very remarkable effect in increasing the strength of soft iron wire. Comparing the breaking weights for the wire quickly broken with those for the same wire slowly broken, it will be seen that in the latter case the strength of the wire is from two to ten per cent. higher than in the former, and is on the average about five or six per cent. higher. The result as to elongation is even more remarkable, and was certainly more unexpected. It will be seen from the tables that, in the case of the wire quickly drawn out, the elongation is on the average more than three times as great as in the case of the wire drawn out slowly. There are two wires for which the breaking weights and elongations are given in the tables, both of them "bright" wires, which showed this difference very remarkably. They broke without showing any special peculiarity as to breaking weight, and without known difference as to treatment, except in the time during which the application of the breaking weight was made. One of them broke with 44 lbs., the experiment lasting one hour and a half; the other with 47 lbs., the time occupied in applying the weight being thirty-nine days. The former was drawn out by 28·5 per cent. on its original length, the latter by only 4·79 per cent.

Tables showing the Breaking of Soft Iron Wires at Different Speeds

I.—Wire Quickly Broken

Rate of adding weight.	Breaking weight in pounds.	Per cent. of elongation on original length.
[1] Dark Wire		
½ lb. per minute	45	25·4
1 ,, 5 minutes	45¼	25·9
,, ,, 5 ,, ...	45¼	24·9
,, ,, 4 ,, ...	44¼	24·58
,, ,, 3 ,, ...	44¼	24·88
,, ,, 3 ,, ...	45¼	29·58
,, ,, 5 ,, ...	44¼	27·78
[1] Bright Wire		
1 lb. per 5 minutes	44¼	28·5
,, 5 ,, ...	44¼	27·0
,, 4 ,, ...	44¼	27·1

[1] The wire used was all of the same quality and gauge, but the "dark" and "bright" wire had gone through slightly different processes for the purpose of annealing.

II.—Wire Slowly Broken

Weight added and No. of experiment.	Breaking weight in pounds.	Per cent. of elongation on original length.
1 lb. per day. I.	48	7·58
,, II.	46	8·13
,, III.	47	7·05
,, IV.	47	6·51
,, V.	47	8·62
,, VI.	47	5·17
,, VII.	46	5·50
,, VIII.	47	6·92 Bright wire.
¾ lb. per day. I.	49	8·50
,, II.	48¼	8·81
,, III.	Broken by accident.	
,, IV.	46	7·55
,, V.	46	6·41
,, VI.	45½	6·62
½ lb. per day. I.	48	8·26
,, II.	50	8·42
,, III.	49	7·18
,, IV.	47	4·79 } Bright wires.
,, V.	46½	6·00 } Bright wires.

It was found during the breaking of these wires that the wire becomes alternately more yielding and less yielding to stress applied. Thus, from weights applied gradually between 28 lbs. and 31 or 32 lbs., there is very little yielding and very little elongation of the wire. For equal additions of weight between 33 lbs. and about 37 lbs. the elongation is very great. After 37 lbs. have been put on, the wire seems to get stiff again, till a weight of about 40 lbs. has been applied. Then there is rapid running down till 45 lbs. has been reached. The wire then becomes stiff again, and often remains so till it breaks.

It is evident that this subject requires careful investigation.

Report of the Committee for effecting the Determination of the Mechanical Equivalent of Heat.—The Committee had little to report this year, the work in progress being the protracted one of supplying a means of correcting errors in the determination of the temperature arising from the temporary changes of the fixed points of thermometers constructed of glass. They had learned with pleasure that an extensive series of experiments had recently been made by Prof. H. A. Rowland, of Baltimore, who, being unaware of what had been done by the Committee, had arrived at an equivalent almost identical with that determined by Mr. Joule.

Report of the Committee appointed for the Purpose of endeavouring to procure Reports on the Progress of the Chief Branches of Mathematics and Physics.—Owing to unforeseen circumstances no meeting of this Committee has taken place during the past year. It seems desirable, nevertheless, in order that the question of the reappointment of the Committee may be fully considered, and that there may be a full expression of opinions on the subject referred to it, that a statement should be made to the Section of the proceedings of the Committee, the more so since, in the hope that greater progress would have been made by this time, no report was presented at the last meeting of the Association.

The first matter discussed by the Committee was the character and general plan of the reports which they should endeavour to procure; the next was to what extent or in what manner the production of such reports could be aided by the Committee. Important contributions to the discussion of these questions are contained in written communications to the Committee from two of its members, Professors Clerk-Maxwell and Stokes. Prof. Clerk-Maxwell writes as follows:—

"Reports on special branches of science may be of several different types, corresponding to every stage of organisation, from the catalogue up to the treatise.

"When a person is engaged in scientific research, it is desirable that he should be able to ascertain, with as little labour as possible, what has been written on the subject and who are the best authorities. The ordinary method is to get hold of the most recent German paper on the subject, to look up the references

there given, and by following up the trail of each to find out who are the most influential authors on the subject. German papers have the most complete references, because the machinery for docketting and arranging scientific papers is more developed in Germany than elsewhere.

"The *Fortschritte der Physik* gave an annual list of all papers, good and bad, arranged in subjects, with abstracts of the more important ones. Wiedemann's *Beiblätter* is a more select assortment, given more in full.

"I think it doubtful whether a publication of this kind, if undertaken by the British Association, would succeed. Lists of the titles of the proceedings of societies and of the contents of periodicals are given in NATURE. These are useful for strictly contemporary science, and I do not think that a more elaborate system of collection could be kept up for long.

"The intending publisher of a discovery has to examine the whole mass of science to see whether he has been anticipated, but the student wishes to read only what is worth reading. What he requires is the names of the best authors. The selection or election of these is constantly done by skimming individual authors, who indicate by the names they quote the men whose opinions have had most influence. But a report on the history and present state of a science has for its main aim to enumerate the various authors and to point out their relative weight, and this has been very well done in several British Association reports, some of which are nearly as old as the British Association.

"There are some branches of science whose position with respect to the public, or else to the educational interest, is such that treatises or text-books can be published on commercial principles, either as books to be read by the free public, or to be got up by the school public.

"There is little encouragement, however, for a scientific man to write a treatise so long as he can, with much less trouble, produce an original memoir, which will be much more readily received by a learned society than the treatise would have been by a publisher.

"The systematisation of science is therefore carried on under difficulties when left to itself; and I think that the experience of the British Association warrants the belief that its action in asking men of science to furnish reports has conferred benefits on science which would not otherwise have accrued to it.

"There are so many valuable reports in the published volumes that I shall indicate only a few, the selection being founded on the direction of my own work rather than on any less arbitrary principle.

"First, when a branch of science contains abstruse calculations as well as interesting experiments, it is desirable that those who cultivate the experimental side should be conscious that certain things have been done by the mathematicians. The matter to be reported on in this case is not voluminous, but it is hard reading, and those who are not experts require a guide.

"Thus, Prof. Challis in 1834 gave a most useful report on the mathematical investigations by Young, Laplace, Poisson, and Gauss on capillary attraction, and Prof. Stokes in 1862 reports on theories of double refraction. This report may, indeed, be accepted as an instalment of the treatises which, if the desire of the scientific world were law, Prof. Stokes would long ago have written. It is meant, no doubt, as a guide to other men's writings, but it is intelligible in itself without reference to those writings. Such a report is a full justification of the existence of the British Association, if it had done nothing else.

"Another type of report is that of Prof. Cayley on dynamics (1857 and 1862). This seems intended rather as a guide in reading the original authors than as a self-interpreting document, though, of course, besides the criticism and the methodical arrangement, there is much original light thrown on the mass of memoirs discussed in it. It will be many years before the value of this report will be superseded by treatises.

"The report of the Committee on mathematical tables deals with a subject which, though not so abstruse, is larger and dryer than any of the preceding. It is, however, a most interesting as well as valuable report, and supplies information which would never have been printed unless the British Association had asked for the report, and which never would have been obtained if the author of the report had not been available.

"There are several other reports which are not mere reports, but rather original papers preceded by a historical sketch of the subject. No special encouragement is needed to get people to write reports of this kind."

Prof. Stokes thus expresses himself on the subject:—

"It seems to me that reports on the progress of science may be of two kinds, with somewhat different objects in view; and in considering the best mode of meeting these objects, it may be well to keep the distinction in view.

"First, there is a report, the object of which is to prepare a sort of repertorium of what has been done in a particular branch of science since the date of the last report of similar character in the same branch of science.

"A report of this kind should present the reader with a brief account of the leading aim and chief results of the various memoirs which have been published within the time on the branch of science to which it relates; the writer should not be expected to criticise the memoirs, except in plain instances of errors or imperfections, but the responsibility of sifting the wheat from the chaff should in the main be left to the reader.

"Secondly, there are reports of a more comprehensive and far more critical character. These should be made at wider intervals, should take a more comprehensive view of the subject, and should be highly critical, sifting out the substantial acquisitions that had been made to the branch of science to which they refer.

"Each kind of reports are of value, though in somewhat different ways. The first aids the individual in keeping himself up to the progress of science around him—a progress in which from his position he may be expected to take part and to exercise influence. They lighten to him the labour of search, but teach him to exercise his own discrimination.

"The second should be a material aid to the student in making himself master of what was really of value, and help him to avoid wasting his time on what was of little importance, and aid him in judging of the relative importance of different lines of research.

"Reports of the first kind may be much promoted by the work of committees. The division of labour lightens the task, and the feeling of co-operation carries a man through labour which otherwise, as the man is likely to have a good deal else to do, he might hesitate to undertake.

"Reports of the second kind eminently demand the hand of a master, and the hand of a master is not always free. I doubt much if the appointment of committees would aid much in the preparation of *good* reports of this class, and unless reports are thoroughly good they are better, perhaps, not attempted. I do not see what is to be done except to work a good man *when you can get him*."

It is evident that the distinction here pointed out by Prof. Stokes has an important bearing on the question of the re-appointment of the Committee. The work required for the production of reports intended simply as systematic records "of the leading aim and chief results" of published investigations, would be merely that of careful compilation. It would not only be possible to divide work of this kind among a considerable number of contributors, but to get it done at all such division of labour would be necessary, and accordingly reports of this class could only be furnished by committees. On the other hand, a report which is of the nature of a critical survey of the condition of knowledge in any branch of science, and is intended to indicate the relative value of different investigations, requires to possess a unity of plan and thought which can only result from its being the work of an individual author possessing a complete mastery of his subject. In such a case the function of the committee would be confined to the suggestion of the subject and to requesting some qualified person to report upon it—a function which hitherto has been discharged by the Sectional Committees of the Association.

Report of the Committee, consisting of Prof. Sylvester and Prof. Cayley, appointed for the Purpose of calculating Tables of the Fundamental Invariants of Algebraic Forms.—The valuable services of Mr. F. Franklin, of the Johns Hopkins University, has computed, under Prof. Sylvester's inspection, the *ground forms* (otherwise called the fundamental invariants and covariants) of binary quantics of the 7th, 8th, and 10th orders respectively, thus rendering the list of tables of such forms complete for quantics of all orders up to the 10th inclusive.

The tables of the *Grundformen* of the seventhic and tenthic are published in the *Comptes Rendus de l'Institut*, 1878, 1879; the table of the *Grundformen* of the ninethic in the *American Journal of Mathematics*, March, 1879, and in a future number of that journal will shortly also appear the intermediary tables of the Generating Functions from which such *Grundformen* are deduced.

These tables, in addition to those previously constructed, will, it is believed, form a valuable, and (for the present) a sufficient, basis for the prosecution of this kind of research in what regards the theory of single binary quantics, leaving a wide field still open for computations of a similar nature connected with systems of binary quantics and binary and semi-binary quantics, single or in systems.

Report of the Committee on Atmospheric Electricity in Madeira, by Dr. M. Grabham.—Daily observations in Madeira extremely monotonous, showing very little variation, though suggesting the importance of a station so uniform in weather for the careful observance of diurnal and seasonal changes. The writer, giving himself to the observation of the regular winds and breezes, traces the steady rise of electricity in the early morning to a maximum at 11·30 A.M., which declines after much steadiness for two hours, at first suddenly and then very gradually towards night.

Remarkable fluctuations are noticed during the formation of the maximum which the writer ascribes to masses of cloud on moist air. A description follows of the daily formation of a thin stratum of cloud during fine calm weather which varies slightly in altitude in accordance with temperature and barometric pressure. The electricity below this cloud is always positive and moderately strong. In the cloud itself it is more feeble but of the same sign. Above the cloud at the station where the observation was taken it was very feeble and irregular but always positive. In warmer weather the vapour does not condense into cloud but appears as a blue transparent haze from above, and presents the same electrical indications.

The writer states that all observations in his own garden were vitiated or mitigated by the presence of lofty trees.

The highest potential was observed upon a rock ninety feet high, a few metres from the shore in the Bay of Funchal.

The thinness of the currents of air constituting sea breezes was demonstrated by flying a kite vertically beyond into the true wind blowing in a contrary direction. Abortive attempts were made to bring down the upper electricity through the lower currents. The electricity of the general north-east wind which is identical with the trade wind was found on the heights at the east end to be uniformly moderate and positive.

At the approach of rain-clouds at the termination of a period of fine weather the atmosphere invariably gives increased readings and no negative observations were recorded.

A short description follows of the L'este, a kind of sirocco to which Madeira is occasionally subject and which blows with great force on certain limited mountain districts bringing sand, birds, and other evidence of a distant origin. This wind is extremely dry, in a temperature of 85° the dew points being depressed below freezing. Electrically this wind in its integrity gives no indication of any change whatever except by faint fluctuations about the earth reading.

The writer also notices a very highly electrical condition during the prevalence of L'este wind, of certain clouds which lie quietly among the mountains, though tossed and tumbled on their upper surfaces; he hopes to be able to connect their forms and immobility with their electrical change.

Report of the Committee on Mathematical Tables, by James Glaisher.—In the course of the year the factor table for the fourth million has been printed and stereotyped, and is nearly ready for publication. The manuscript of the factor table for the fifth million is complete. The table for the sixth million is complete as far as the factors entered by the sieves are concerned, but the factors obtained by the multiple method still need entering, and the whole has to be verified. The mode of calculation was described in last year's report, and a more complete account will appear in the introduction to the fourth million. The present report contains the result of the enumeration of the primes in the fourth million, and a list of long sequences of composite numbers occurring in it. The report also contains a table of the first seven Legendrian coefficients, viz., $P^n(x)$ for $n = 1$ to $n = 7$, where

$$P^1(x) = x,\ P^2(x) = \tfrac{1}{2}(3x^2 - 1),\ P^3(x) = \tfrac{1}{2}(5x^3 - 3x),$$
$$P^4(x) = \tfrac{1}{8}(35x^4 - 30x^2 + 3),\ \&c.,$$

each for a hundred values of the argument.

Report of the Committee on Luminous Meteors, by James Glaisher.—After recording the regret the Committee felt at the loss of two of the most active workers—Mr. Greg by his retirement, and Mr. Brooke by death—the report stated that the very unfavourable weather had generally caused only very meagre views of the annual star showers of October, December, January, and April to be seen. The major showers of August had also been hidden from view, owing to the unfavourable weather. The report then dealt in detail with the accounts of conspicuous detonating fire-balls that had occurred in the United States on August 11 and December 18, 1878, and on January 27, 1879; in Bohemia and Saxony on January 12, 1879, and in England on February 22 and 24, 1879, the real paths of all of which had, to a greater or less degree of certainty and closeness, been approximately ascertained. The rest of the report was devoted to a description of the past year's aërolites. The expected return of Biela's comet to its perihelion in the present year, leading a shower of shooting stars to be looked for with much confidence among astronomers on November 27 next, is to be taken advantage of to report next year on meteor showers. As in former years the Committee were under great obligations to Prof. A. S. Herschel for the labour he had bestowed on the report.

Report of the Committee for Calculating Tables of Sun-heat Coefficients, by Rev. Dr. Haughton.—A table showing the total heat received by various latitudes from the sun in the course of a year had been formed; and the work would be completed by next year. The results already obtained have appeared in the *Proceedings* of the Royal Dublin Society.

Report of the Committee consisting of the Rev. H. T. Barnes Lawrence, Mr. Spence Bate, Mr. H. E. Dresser (Secretary), Mr. J. E. Harting, Dr. Gwyn Jeffreys, Mr. J. G. Shaw Lefevre, M.P., Prof. Newton, and the Rev. Canon Tristram, appointed by the Council, for the purpose of Inquiring into the Possibility of Establishing a Close Time for the Protection of Indigenous Animals.—Your Committee has gratefully to acknowledge the resolution of the Council of the Association, whereby your Committee has been not only reappointed but also instructed to report to the Council in case of any action being required. Your Committee begs leave to state that no such emergency as was provided for by this instruction has arisen since the presentation of its last report. Notwithstanding complaints that are occasionally heard, your Committee believes that public opinion continues strongly in favour of the close time principle, as applied to indigenous animals; and on the part of Her Majesty's Government no steps have been taken to carry out the recommendations of the Scottish Herring Fishery Commissioners, upon which your Committee deemed it its duty to animadvert last year. The Bird Preservation Acts, though doubtless evaded in some places, in general appear to work well, and to be enforced without difficulty when occasion requires. Having regard to future contingencies, your Committee ventures to solicit its reappointment with the instructions as to reporting to the Council in case of emergency.

Report of the Committee consisting of Mr. Sclater, Dr. G. Hartlaub, Sir Joseph Hooker, Capt. F. M. Hunter, and Prof. Flower, appointed to take Steps for the Investigation of the Natural History of Socotra.—The Committee have not held any formal meetings, but have been in frequent communication with each other on the subject.

The best time for the exploration of Socotra being from November to March, the Committee were not able to make the necessary arrangements last autumn. Next winter, however, they believe that Col. H. H. Godwin-Austen, than whom no more competent naturalist could be found, will be able to undertake an expedition to Socotra, and to make a thorough investigation of its natural history. Col. Godwin-Austen has applied to the Surveyor-General of India for the use of some of the assistants on his staff, and proposes to make a complete topographical survey of the island during the expedition.

It is estimated that the total cost of the expedition will be about 300*l*. Of this 100*l*. granted by the Association last year, has been received by the Committee and deposited in the London and County Bank at interest. The sum of 175*l*., having been devoted to this same purpose out of the Government Fund of 4,000*l*. administered by the Royal Society, has been paid to Col. Godwin-Austen, and has been added to the account at the London and County Bank.

There remains, therefore, only 25*l*. requisite to complete the sum of 300*l*., which the Committee consider will be required for the expedition.

The Committee request that the Committee for the investigation of the Natural History of Socotra may be re-appointed with the additional name of Col. H. H. Godwin-Austen, and that the balance of 25*l*. necessary to complete the estimate of expenditure may be placed at their disposal.

Report of the Committee on an Instrument for Detecting Fire-damp in Mines, by Prof. G. Forbes.—From the rough model shown last year the Committee had constructed two new instruments, which appeared to them to answer the purpose of measuring the quantity of fire-damp in a coal mine. The one was of a large size, and was worked by an electric battery. The other was small, portable, easily worked, and it answered all the purposes for which it was required. Both instruments were founded upon the facts that sound travels quicker in light gases than in dense ones, and that air which is contaminated with fire-damp is lighter than pure air. The velocity of sound in different qualities of air was compared by noting the lengths which must be given to a brass tube to cause it to resound to a tuning-fork. The accuracy of the instrument was such that the percentage of fire-damp could be determined with an error of considerably less than 1 per cent. On Monday the Committee were enabled to descend the Wharncliffe Silkstone Colliery, in the neighbourhood of Sheffield, by the kindness of the manager, Mr. George Walker, who accompanied them with a number of gentlemen interested in the experiments. This pit was at a depth of 200 yards. Mr. Walker had kindly arranged to stop the ventilation and the pit at the end of the workings. After proceeding for a mile through the galleries they reached this spot, where they hoped to find a large amount of fire-damp. But only a slight quantity was to be found, the Davy lamp generally showing but a feeble blue cap, and the Forbes indicator registering only small percentages. Disappointed here, they were taken by Mr. Walker to another working, where it was thought possible there might be some gas. In a crevice in the roof a flow of gas was found, forming a stratum of light gas. The instrument indicated quantities which gradually increased, as the tube got filled with the air in the crevice, from 14 to 28 per cent. But the small quantity of gas rendered the experiment unsatisfactory, and the Committee were then taken to a disused part of the mine, where it was known there was a blower. Gas in sufficient quantities was found, and the instrument registered gas with more readiness than the Davy lamp. But the greatest quantity registered was 6 per cent., or twelve times the smallest quantity which the indicator detects. There was in the present form of the instrument a difficulty in filling the tube with the air of the place under examination, and the Committee considered that it would be well to alter the instrument so as to obviate the difficulty. From the experiments they could assert that this instrument was capable of detecting and measuring fire-damp even in small quantities.

SECTION A—MATHEMATICAL AND PHYSICAL

On Lightning Protectors for Telegraphic Apparatus, by W. H. Preece.—For many years it was not the practice in England to protect telegraphic apparatus from the injurious effects of atmospheric electricity because the damage done was so insignificant, and because the remedy was found to be worse than the disease. But as telegraph systems increased, as the country became enveloped in one vast network of wires, it was found that the damage done became considerable, until, in fact, about 10 per cent. of the apparatus in use were in one year damaged.

Lightning protectors then became essential. Many forms were tried based on the fact that when a discharge takes place through a non-conductor such as dry air, at the moment of discharge the resistance along the line of discharge is practically nothing, and therefore all the charge is conducted away. According to Faraday, "the ultimate effect is exactly as if a metallic wire had been put into the place of the discharging particles" ("Researches," series xii.). Most of those tried failed.

The survival of the fittest has been exemplified in the "plate" protector. In this form—one of the earliest introduced—one thick plate of brass is in connection with the earth, and another similar plate in connection with the line, is placed above it, but separated from it by paper, or by insulating washers. The lightning entering the wire bursts across the paper or air-space in preference to passing through the apparatus, and thus escapes to earth.

An important modification of this plate discharger has been made by Dr. Werner Siemens, who, by serrating, or grooving with a pointed tool the opposing faces of the two plates at right angles to each other, converted them into a conductor which was supposed to be one composed of an infinite number of opposing points. The remarkable action of points in facilitating discharge is well known, and their introduction into lightning protectors occurred very early in the annals of telegraphy by Mr. C. V. Walker, F.R.S.

Messrs. Siemens's arrangement, very pretty in theory, never carried conviction of its value to the mind of the author, because protectors so prepared never singled themselves out as evidently superior to others that were not so prepared, and while the intersection of the grooves certainly formed mathematical points, they did not form physical or mechanical points, and it is upon the action of this latter kind of points that such remarkable electrical effects are produced.

Dr. Warren de la Rue having very kindly placed his well-known battery of 11,000 cells at the disposal of the writer, he prepared four plate-protectors identical in dimensions, excepting that two were serrated, and two were not. The two plates were separated from each other by narrow ebonite washers ·01 inch thick. The upper plate was placed in connection with the positive pole, and the lower plate with the negative pole. The number of cells were increased until a continuous current of electricity flowed.

1.—*Plain Plates*

Number of Cells.	Effects produced.
1,000 ...	Slight sparks commencing on completing circuit.
1,080 ...	Sparks evident.
1,200 ...	Sparks frequent and abundant.
1,500 ...	Continuous arc.

2.—*Serrated Plates*

Number of Cells.	Effect produced.
1,000 ...	Sparks just commencing on making contact.
1,080 ...	Sparks evident.
1,200 ...	Sparks frequent.
1,500 ...	Continuous arc, but fitful.

2,000 cells in each produced a continuous stream of electricity. The effect with 1,500 cells was decidedly more marked with the plain plates than with those serrated. The experiments were extremely pretty, and very decided in their character. Hence it appears that grooving is not only of no use, but that it rather deteriorates the value of the protector.

These experiments confirm very decidedly the accuracy of the figures obtained by Dr. Warren de la Rue and Mr. Müller on the striking distance between two flat disks given by them in their paper read before the Royal Society (*Phil. Trans.*, vol. 169), where it was shown that 1,200 cells struck across ·012 inch. Here 1,000 struck across ·01 inch, which agrees perfectly with the curve produced by those observers.

It is the practice in the Post Office telegraph department to keep these plates apart by thin paraffined paper ·002 inch thick, so that the air surface is really much thinner than that experimented upon, and the striking difference of potential only 250 volts.

Messrs. De la Rue and Müller have shown that for points and various kinds of surfaces opposed to each other, plane surfaces act the best for potentials less than 1,500 volts, and that points are only efficient for high potentials. Now as it is doubtful whether atmospheric electricity causes much higher potential than 1,000 volts, it is clear than plane surfaces are the most effective for protecting apparatus. It is quite certain that such plates, plain and smooth, separated by an air space ·002 inch thick, will form very efficient lightning protectors.

The author is very much indebted to Dr. Warren De la Rue for the performance of the experiments in his laboratory.

Experiments made to determine the Friction of Water upon Water at Low Velocities, by Rev. S. Haughton, M.D., D.C.L.—The author's intention, in commencing the experiments, was to ascertain the co-efficient of tidal friction, and also to ascertain the elevation of water at the equator or pole, necessary to cause a current; and both these results he hopes to secure with some approach to accuracy.

The experiments were conducted by means of a spherical ball of granite, unpolished, which was suspended by a pianoforte wire, and allowed to hang freely; from the brass collar by which the ball was suspended an index projected on each side, the pointed ends of the indices traversing a graduated horizontal circle, whose centre corresponded with the line of suspension. The suspended ball was immersed in water contained in an iron tube.

On the Tension of Vapours near Curved Surfaces of their Liquids, by G. F. Fitzgerald.—The paper is intended to give a physical explanation of the fact that the tension of a vapour in

contact with the surface of its liquid when that surface is convex or concave is greater or less respectively than when flat. It rests upon the assumption that evaporation is not purely superficial but that molecules are emitted from a certain depth beneath the surface of a liquid. From this it follows that the chances of escape of a molecule from a given depth below a convex surface are greater, and from a concave less than from a flat one. Taking the depth from which emission takes place as very small compared with the radii of curvature of the surface, the author has deduced the same formula for the increase or diminution of tension as Sir W. Thomson deduced from capillary phenomena.

Etherspheres as a Vera Causa of Natural Philosophy, by Rev. S. Earnshaw, M.A.—The author, assuming an admitted parallelism between the phenomena of light and heat, proceeds by means of three hitherto overlooked propositions in natural philosophy to establish the universal existence of what he has denominated *etherspheres*, the third of his propositions being—"Every atom of matter in the universe is surrounded by an ethersphere of its own." The following is the system of nature which he finds sufficient for his purpose:—

1. In nature there are two distinct substances, matter and ether, neither of which has any power to attract or repel the other.

2. Matter consists of atoms which attract each other with forces varying according to the Newtonian law (distance)$^{-2}$.

3. The atoms of bodies of the same kind are alike in all respects; atoms of bodies of different kinds differ from each other in size, and possibly also in other respects, such as shape, &c.

4. Atoms, whether of matter or of ether, are incapable of experiencing any change of figure or dimensions; and they are all assumed to be of such geometrical forms as cannot fill space.

5. From the phenomena of light it has been inferred that atoms of ether repel each other with a force varying as (distance)$^{-4}$.

6. Every atom of matter is impervious to ether, and acts on ether in no other way than by pressure of contact.

7. A portion of space filled with matter is necessarily void of ether; and all space void of matter is pervaded by ether.

8. The enormous velocity of light in free space has led to the opinion that very great must be the repulsive power of ether on ether; and it seems to follow from this that an ether atom will experience great difficulty in moving from one part of the ethereal medium to another. Except as waves and currents, ether motion will be under great restraints, and especially shall we see this when we also remember the high power (viz., the fourth) of its inverse law of force.

9. In free space light is believed to be transmitted with the same velocity in every direction, and from this we infer that the atoms of ether are all spherical in form.

The following is the author's definition of an ethersphere:—

All space not filled by matter is pervaded by ether, so that every atom of matter is surrounded by ether, but this is not what is included in the word "ethersphere." The author shows that if any portion of space be rendered void of ether from any cause whatever, that space has become void of the repulsive forces which were centred within it, and that, consequently, when these forces are taken away the medium outside the space will draw closer towards that space; and if the space be occupied by an atom of matter, the density of the surrounding ether will be greater than before, and the ether, being in contact with the atom at its surface, will press upon it. This *excess* of ether about the vacant space above its original quantity constitutes the ethersphere; and though this gathering together of ether about the space now occupied by the atom is a consequence of the presence of the atom, it is in no way owing to its action on the ethereal medium.

The author then argues that if every material atom, so must every compound system of atoms, *i.e.*, every material body, whether gaseous, liquid, or solid, have an ethersphere, which not only surrounds the whole body, but also penetrates the interstitial spaces of the body which lie between its atoms.

By means of these etherspheres the author believes the phenomena of heat may be satisfactorily accounted for, on the supposition that the ethereal medium is the medium of heat as well as of light. They are shown in the original memoir itself to have a remarkable bearing also on the phenomena of magnetism, electricity, galvanism, and the various sciences connected with the agency of imponderables. He therefore concludes that etherspheres constitute a *vera causa* the existence of which in nature is as certain as is that of the ethereal medium itself, about which no philosopher expresses doubt in the present day.

On the Fundamental Principles of the Algebra of Logic, by Alexander Macfarlane, M.A., D.Sc.—In a work recently published, entitled "The Algebra of Logic," the author has investigated anew the foundations of that branch of mathematical analysis which was originated by Boole in his celebrated treatise on "The Laws of Thought." In making this inquiry the author has studied the contributions to the subject made by Harley, Venn, Jevons, and others.

The difficulty and apparent irrationality of Boole's calculus is due to the fact that it is founded on the old and inadequate theory of the operation of the mind in reasoning about quality. That theory supposes that the mind, in forming a compound conception out of two simple conceptions, necessarily considers the second of these as limited by, and in a measure dependent upon, the first; in the theory which the author advances it is maintained that the mind may, on the other hand, form compound conceptions in which the second element is entirely dependent on the first; and, on the other hand, compound conceptions, in which the two elements are mutually independent.

The author considers that the fundamental notion in this branch of analysis is that of a collection of homogeneous objects having differentiating characters. The collection of objects, so far forth as they are homogeneous, may be denoted by u (as they form the universe considered in the particular investigation); a differentiating character may be denoted by a small letter, as x. The symbol x applies to, and is entirely dependent upon, u. The arithmetical value of u is the number of the objects considered, and may be singular, plural, or infinitely great. The arithmetical value of x is the ratio of the number of the objects which have the character x to the whole number of objects considered. The author then explains the meaning of the letters and symbols in this system of logic.

On Synchronism of Mean Temperature and Rainfall in the Climate of London, by H. Courtenay Fox, M.R.C.S.—The object of the paper is by the examination of a long series of facts to ascertain whether there be any law which regulates the *occurrence at the same time* of extremes of temperature and rainfall, so far as we can ascertain it in the English climate.

The facts used are the rainfall and mean temperature as for the Royal Observatory in each month and season for 66·67 years. The mean temperature from 1813 to 1840 is that computed by Mr. James Glaisher, F.R.S., (*vide Philosophical Transactions*, 1850, part 7); and from 1841 to the present time, it is from direct observation. The rainfall from 1830 to 1840 is derived from sundry observations about London collated by Mr. George Dines, and from 1841 to the present time it also is from direct observation at the Greenwich Observatory.

The author has constructed tables *for each month*, in which the sixty-seven (or sixty-six) years are arranged in the order of the mean temperature of that month, beginning with the coldest and ending with the warmest, and also arranged in like manner in the order of their amount of rain. The sixty-seven years are then divided, as nearly as can be, into five equal sections, of which the middle section is termed average years; the division on each side of the average are termed cold and warm, dry and rainy, respectively; while the extreme sections are qualified by the word *very*, being called very cold, very warm, very dry, and very rainy, respectively. We have thus a pretty fair division of the series of years in both these characters. What has been done for each month has been also done on exactly similar principles for each season and for the whole year. The results found were:—

1. In the winter months, cold tends to be synchronous with dryness, warmth with large rainfall.

2. In the summer months, cold tends to be accompanied by much rain, warmth by dryness.

3. Rainy years tend to be either very cold or very warm, whilst years of drought tend to assume an average temperature.

Experiments on the Influence of the Angle of the Lip of Rain Gauges on the Quantity of Water Collected, by Baldwin Latham, C.E., M. Inst. C.E., F.G.S., F.M.S.—The author having observed that, in the ordinary pattern of the Glaisher gauge, in high winds the rain was often driven up the sloping lip and into the gauge, thought that if the rim of the gauge were made very acute, having a sharp knife edge and equal angles both inside and outside the gauge, any rain which might strike upon the outer angle on one side of the gauge might be thrown into the

gauge. Rain striking upon the inner and opposite side of the gauge would be thrown out, and so an equilibrium rim would be constructed, as the gain on one side would be balanced by the loss on the other side.

With this view, the author had an 8-inch gauge made and tested alongside of an 8-inch Glaisher gauge. The sloping lip of the Glaisher gauge had an angle of 45° from the perpendicular, and the rim of the equilibrium gauge was ·8 in. deep, ·18 in. in thickness, sloping off on both sides at an angle of 3° from the perpendicular. Both gauges were fixed at Croydon, 4 feet above the ground, and 259 feet above Ordnance datum. These gauges had been working side by side for 551 days, from January 5, 1878, to July 5, 1879, during which period rain or snow has fallen upon 306 occasions. Upon 43 occasions it was found that the rain collected in the Glaisher gauge exceeded, by a small amount, the rain in the equilibrium rim-gauge, and on two occasions the quantity in the new gauge exceeded that in the Glaisher gauge. Upon 261 occasions the rain in both gauges was absolutely equal. On all occasions, it should be observed, the rain from both gauges was invariably measured in the same graduated measuring glass. On the 45 occasions when the Glaisher gauge collected most rain, the wind without exception was high. On the two occasions when the equilibrium rim-gauge collected more rain than the Glaisher gauge, it was probably due to dew, the equilibrium gauge presenting a larger surface for condensation than the other gauge. As the Glaisher gauge was not calculated to contain snow, all falls of snow are recorded in the equilibrium rim-gauge, which is constructed to hold about one foot in depth of snow.

The total quantity of rain collected in the Glaisher gauge during the period of observation, plus the snow as caught in the equilibrium rim-gauge, was 46·68 in., and the quantity collected in the equilibrium rim-gauge was 46·45 in., showing a difference of but half per cent. In all probability, however, the small excess measured by the Glaisher gauge would tend to compensate for the losses by evaporation in periods of small rainfall and at other times, and therefore, as a measuring gauge, the Glaisher pattern of gauge, when tested by a gauge of the description mentioned, gives results in practice which may be taken as correct.

Summary of Results

Date.	Total number of days' experiments.	Number of days when rain fell.	Amount of rain collected by Glaisher gauge.	Amount of rain collected by equilibrium rim-gauge.	Times when Glaisher gauge in excess of equilibrium rim-gauge.	Times when equilibrium rim-gauge in excess of Glaisher gauge.

On the Retardation of Phase of Vibrations transmitted by the Telephone, by Prof. S. P. Thompson.—It was predicted from theoretical considerations by Dubois-Reymond that a difference of phase, amounting to a quarter of a complete vibration, would be found to exist between the diaphragms of two associated Bell telephones, the receiving telephone being a quarter of a vibration behind the transmitter. A more complete theory, worked out independently by Helmholtz and Weber, gave a somewhat contradictory result, and required only a small difference of phase. Recently König in a series of delicate experiments, effected an optical comparison by the method of lissajous of the vibrations of a pair of telephones, replacing the vibrating discs by tuning-forks armed with mirrors. The experiment is a delicate one, and is performed under condition not free from objection. The author has proposed the following method of observing. A pair of Bell telephones are suspended by wires of about a metre in length, so as to oscillate as pendulums, to frames so disposed as to avoid the possibility of any mechanical transmission of the vibrations. Below the point of rest of each telephone, and at some little distance from it in the plane of its swinging, is placed a steel magnet. After the lengths of the wires have been so adjusted that the telephones will swing in identical periods, one telephone is set swinging. As it alternately approaches and recedes from the magnet, the induced currents traversing the second telephone set it swinging. In every case the difference of phase observed amounted to one quarter.

In the case of those telephones which transmit vibrations by varying the resistance of the circuit, instead of varying the electromotive force, there is no such retardation of phase produced in the ordinary electromagnetic receiver. If, however, the current so transmitted is first passed through an induction coil, a retardation of phase of one quarter is produced, and in the case of several successive inductions the retardation amounts to an additional quarter for every additional induction. This remark applies only to vibrations of harmonic and quasi-harmonic type. Vowel sounds, which consist of compound harmonic vibrations, are unchanged to the perception of the single ear, which is unable to distinguish differences of phase, or between compound sounds which differ from one another only in the difference of phase of their components. The vibrations of consonantal sounds, on the contrary, depart more and more widely from their original type at each successive induction.

In the case of Edison's motographic or electro-chemical receiver, the velocities, not the displacement of the disc, are proportional to the strength of the currents received. Hence vibrations already retarded one quarter in transmission, as is the case with those of the carbon transmitter in conjunction with its induction coil, always used with this instrument, are restored to their primitive phase. The vibrations of this receiver therefore agree in type, not with the vibrations of the induction current (which correspond to the derived function of those of the original vibration), but with those corresponding to the function of which the vibrations of the induction current are the derivate; that is to say, they agree in type with the primitive vibrations of whatever form. Hence in the receiving telephone of Edison consonantal sounds which depart widely from the purely harmonic type are better rendered than in a telephone which like that of Bell both retards the vibrations in phase and alters them in type.

On some New Instruments recently constructed for the Continuation of Researches on Specific Inductive Capacity, by J. E. H. Gordon, B.A.—Mr. Gordon exhibited and explained the following new instruments which he has arranged during the last year:—

1. A miniature five-plate induction-balance, similar in principle to the large balance exhibited at the Dublin meeting, but intended for the examination of crystals and other precious substances which cannot be obtained in sufficiently large quantities for the large balance.

The large balance requires the dielectric plates to be 7 inches square and $\frac{1}{2}$ to $\frac{3}{4}$ inch thick. For the small balance it is sufficient to make them 2 inches square and $\frac{1}{8}$ inch thick.

2. A gauge for measuring the thickness of the dielectric plates to $\frac{1}{1000}$ inch.

3. A new form of quadrant electrometer for use with the small induction balance.

The capacity of the smaller plates of the little induction balance is so minute that when they are attached to the quadrants of the electrometer of ordinary construction (Elliott pattern) disturbances in them produce hardly any effect on the needle, on account of the much greater capacity of the quadrants of the electrometer.

In order to construct an electrometer whose quadrants should

have very small capacity, and which should yet be very sensitive, the author has arranged the quadrants as pieces of a flat disk, only 1 inch in diameter, and the needle has been bent round them so as to be acted on by both their upper and lower surfaces and their outside edge.

4. A new rapid commutator.

This was invented by Prof. Cornu, of the École Polytechnique, Paris, who had the great kindness to devise it for the author of this paper, who, when M. Cornu took up the matter, had just constructed three different instruments for the experiments for which this one is intended, all of which had proved unsuccessful.

Some preliminary experiments with M. Cornu's instrument have shown that it promises to be entirely satisfactory. It can be used with either the large or small induction balance on the one hand, and with a Holtz machine or battery of 500 or more cells on the other. It reverses the electrification of the plates of the balance eighteen times per second, and between each reversal, short circuits, and puts to earth both poles of the induction balance and both poles of the battery. By altering two screws it can be arranged to short circuit and put to earth the poles of the induction balance only, and to insulate the battery poles.

5. Driving-wheel for the Cornu commutator.

All the instruments have been constructed by Mr. Kieser, of the firm of Elliott Brothers.

SECTION C

GEOLOGY

Opening Address by Prof. P. Martin Duncan, F.R.S., Vice-President of the Geological Society, President of the Section

Everyone who is interested in the science which is especially considered in this Section of the British Association for the Advancement of Science must be impressed with the importance of the geological construction of this district in determining its physical geography, in producing the features of its landscapes, and in originating and developing many of the industries of the busy town of Sheffield.

It was inevitable that you should be addressed, at the commencement of your labours, upon the subject of the carboniferous formation, especially as the intention of this peripatetic congress is to advance science amongst those who require it. It will therefore be my privilege to bring before you some of the more important generalisations of the day, and some other considerations regarding the great formation which is so fully developed in this part of England; trusting that whilst many of you will submit to be reminded of the results of the labours of the men who have established our science and of those of yourselves, some who desire further information than they have hitherto obtained may be advanced in knowledge.

Of all geological formations, the carboniferous is the most important to mankind at the present time, and the most interesting to the student. It gives the earliest clear and definite idea of a land surface on the earth, or rather of the existence of many lands; for they are to be traced here and there from high up in Arctic latitudes to Australia, and from the West of America to Eastern Asia. It offers evidence of the existence, even in those remote days as in the much later miocene age, of astronomical conditions which do not now prevail. It yields proofs of the persistence of a vast lowland flora during extraordinary vicissitudes of the relative level of land and sea, and of the existence of a fauna remarkable for its great fish and amphibia, and whose air breathing mollusca and insecta are of surpassing interest, forshadowing as they do many recent forms. And its study indicates that the movements of the crusts of the earth, which occurred during and terminated the age, were of the grandest kind, and have been of the greatest importance to mankind, destroying, it is true, all the vestiges of a large part of a volume of the earth's history, but bringing coal within the reach of the explorer and miner.

This world-wide formation, usually very thick everywhere, has all the evidences of having lasted during a vast age, and there are present in it the relics of sea floors, of shallow seas and estuaries, of land surfaces, rivers, and marshes. The volcanic activity of the age was great, and is capable of demonstration.

So deep are some of the sediments composing the carboniferous formation in different parts of the world, that the idea of exact contemporaneity is not necessarily much modified. It was in all probability "coal time" universally, and for a long duration. But the beginning of the period was not synchronous in different parts of the earth, neither was the ending. The Devonian age lasted longer in some parts of the earth than in others; and the crust movements which so altered the physical geography of the carboniferous hills, dales, and swamps as to develop a new aspect of nature, terminated the period sooner in some quarters of the globe than in others. In such a locality, however as Eastern Hindostan, the duration of a carboniferous type into the secondary ages is apparent. Hence, in spite of a recognised general contemporaneity, it must be credited that carboniferous, Devonian, Permian, and later deposits were accumulated early and late during the lapse of one great age in distant parts of the globe.

The duration of the carboniferous age in the broadest sense, may be attempted, but with no great success, to be estimated by the time which must have elapsed during the world-wide dispersion of identical species; and its biological relation to the preceding and subsequent formations may be appreciated from the fact that the carboniferous flora, lasting as it did from the bottom to the top of the formation, was foreshadowed in the Devonian, and that it founded the mesozoic. Thus the Australian, Himalayan, British and North and South American marine strata of the carboniferous age contain many identical species of Brachiopoda—the variation from the English types, which were the first described, being very slight. Amongst the corals some forms are equally widely diffused. Now, according to what occurs in nature at the present time, the movements of species from one locality to another by ova, or by wafting of the young—the only method of the lateral or horizontal progress of the brachiopoda—for instance, is impeded by many physical conditions, and is constantly rendered abortive by predaceous and obstructive living forms, and by what is called the strugggle for existence. Migration, or rather the extension of the locality of the species, for the first term implies much more than was or is ever done, is so rarely possible to any great extent under the present complicated natural history and physical condition of the earth that the mind fails to grasp the time which would lapse between the commencement of the dispersive process and the establishment of identical species, even a few thousands of miles off. To bring the subject a little nearer, however, it is necessary to consider that the Arctic and Antarctic cold areas and the frigid bathymetrical ocean zones did not then exist, and that the movements of the crust, producing extension of coast lines, were exceedingly frequent during the age, and must have facilitated the dispersion of littoral and moderately deep sea species.

The dispersion of the species of the numerous cryptogamous plants was doubtless rapid in relation to that of the animals, for their spores could be wafted to a great distance by wind, and they do not appear to have had much to struggle against. With the coniferæ it was different, and the examination of the methods in which fir trees spread in favourable localities, at the present time is very suggestive of exceeding slowness of dispersion. Nevertheless, the cones of the coniferæ were carried here and there by water during the carboniferous age.

To add to the notion of the long duration of the age it must be remembered that a succession of identical floras occurred nearly on the same areas, involving repetitions of growth and of migration.

The growing of the vegetation of each swamp and lowland tract, its accumulation and covering up with sand, shales, and gravel, occupied much time, and the last process involved the destruction of considerable breadths of plant life. The formation of under-clay or warp, if the similar occurrences of the present day be taken as examples, occupied much time, and then a lapse occurred whilst the nearest flora supplied a new vegetation to the virgin soil.

In some instances the recurrence of vegetation was evidently the result of spreading from no great distance; but in others so great a depth of sediment separates the consecutive deposits of coal, and the great subsidence which took place is so evident, that the migration must have been from a considerable distance, and must have occupied commensurate time. In endeavouring to appreciate this lapse of time, it must be remembered that, even on the small surface of the United Kingdom, there was land on some parts during the whole of the carboniferous age notwithstanding the diversity of the deposits and the frequent occurrence of marine conditions.

It would appear that prior to those movements of the earth's

crust which terminated the physical geography of the Devonian age, three elevated tracts of land crossed the kingdom from west to east, and that there were mountainous regions running northwards and north-westwards, including North Wales, Western Ireland, and much of the North Atlantic.

The southern high land barrier passed somewhere in the direction of the Bristol Channel, and then to the east and slightly to the south, having a somewhat definite continuation with the Ardennes. The central barrier, or high land, passed from Shropshire eastwards by Leicester, and then to the coast; and the northern was formed by hills in the present lake district, extending eastwards. On the south of the southern high land, the marine Devonian accumulated in a coral sea, and to the north of it and between it and the central barrier the old red lakes obtained their water supply and sediment from the Welsh hills of the period. North of the central barrier, interrupted lakes and land occurred, and also to the north of the northern barrier. The dry land and the barriers and hills were formed by sub-rocks of Silurian and Cambrian age.

There is no evidence to indicate that the southern barrier was of great height at the end of the Devonian period, but there is some which points out that the first physical change which initiated a new aspect of nature—the carboniferous—was a general subsidence of the region. The coral reefs sank below the bathymetrical zone of the composite forms, and the sea breached the barrier. The southern old red lake began to have its waters impregnated with salt, and its great ganoid fish were replaced by the cestraciont sharks of the age. These left their remains in the bone bed at the base of the lower limestone shales, which are the earliest of the carboniferous series there. The irruption of the sea appears to have taken place to the north of the central barrier also, and the subsidence was great there, a limestone with some sandy strata forming gradually. In the north and north-east, in the present district of the Tweed, deposits collected in shallow water, and vegetation grew which formed the coals at the base of the great Scour limestone.

On the same and on slightly higher horizons are the coals of Fallowfield, Tindal Fell, and Heskett. These are the earliest evidences of the carboniferous vegetation, and it was doubtless in full vigour whilst marine conditions existed to the south.

Probably the high lands constituting the barriers were not covered during the subsidence, which permitted the accumulation of the marine deposits of the carboniferous limestone age. For close to the coal-fields near the central barrier, and which rest on upper Silurian rock, borings here found the remains of carboniferous plants on the palæozoic rock without the intervention of any sediments.

Now the depth of the deposit of limestone about this central barrier is great, and the question arises how was it produced in the immediate proximity of land which was not covered by sea, and which does not appear to have sunk contemporaneously with the sea floor close by? Sinking along definite lines bounded by faults is the only means by which this can be explained; and this suggestion, which was a favourite topic with Phillips, is all the more probable, when it is remembered that the area of accumulation to the north of the barrier was one of vast subsidence during the consecutive ages of the grits and coal measures, whilst there was land still further north. If the stability of one and the instability of the other are not conceded, the original height of the barriers must have been stupendous and beyond example, so far as the size of their bases is concerned.

There are many examples of what I resolved to call in a presidential address before the Geological Society areas of comparative instability and which relate apparently to radial upheaval subsidence along long lines of country where movement has been rare. An instance on the grandest scale is seen in the history of the Himalayas in relation to the peninsula to their south and south-west. For whilst this last area was land during a vast age, that of the Himalayas was repeatedly a marine tract, and suffered subsidences and elevations.

Still further north and beyond the northern barrier, in the Scottish area, carboniferous plants lived a little later, and after a subsidence which permitted the lower calciferous series to accumulate. The lowest coals of the basin of the Clyde are of this age, and the accompanying clay, ironstone, and the fresh water limestones and gigantic fish of Burdie House are all indications of terrestrial conditions. All these evidences of carboniferous vegetation occur in the geological horizon of the carboniferous limestone and Yoredale series.

Never entirely free from sandy impurities the carboniferous limestones north of the central barrier gradually became covered with a thick arenaceous series containing here and there marine fossils and traces of coal plants. These are the Yoredale strata, which consist mainly of the sediments of a somewhat distant north-westerly land, the plants of which were carried to sea by rivers and deposited here and there on the sea floor. It would appear from the evidence collected by the Geological Survey that, after a very considerable thickness of these rocks had collected, either a filling up of the shallow sea or a slight upheaval of the floor occurred, for denudation of their surface happened, considerable depressions and ridges being produced on it. On those spaces and ridges, and indeed on the whole surface of the Yoredale rocks, collected strata which are popularly called the millstone grits, so well seen west of Sheffield. All the depths of this great land wreckage, consisting of silicious and felspathic sandstones and shales, accumulated on a sinking area, some near land and the rest in deeper places. And here and there coal seams are found intercalated, being evidences of the existence of contemporaneous vegetation. Some of them are workable, and others are only valuable as evidences of the existence of the vegetation of the age; many are placed on a hard silicious or ganister bed, but some have an underlying fire-clay. They are very usually covered with deposits containing goniatites and aviculopecten, which doubtless are the remains of marine organisms.

Admitting, therefore, that some of this millstone grit coal may be the result of the drifting and sinking of the vegetation from off lands rather remotely situated, it is still evident, from the existence of the under-clays elsewhere, that some of the grits, by silting up, or by slight upheaval, above sea level, formed the subsoil of swampy ground on which vegetation grew. This approach of the millstone grit sea floor to above sea level was decided enough in the region of the great coal-field around us, for a conglomeratic rock—the rough rock—occupies a somewhat definite horizon on the top of the series.

This rough rock collected in shallow water, and it is important to the geological surveyor, for it formed the base on which the coal measures, proper, rest; and it is suggestive to the physical geologist that a general and wide, but not great, upheaval took place which removed the ocean of the day further off, and which determined a total change in the direction of sediment-depositing currents.

Hitherto the greatest thickness of the sediments of the millstone grit age had been towards the north-west, and the direction of the currents had been from north-west to south-east, but subsequently, as has been suggested from very strong evidence by Sorby, the depositing currents of the next age had no very definite direction. But the carboniferous land of this part of Europe was not yet remote from the sea. Much of it was on the borders of estuaries, and the aspect of nature was probably that of wide flats of grit covered usually by terrestrial vegetation and occasionally overwhelmed by sea. In fact, both practically and theoretically there is much difficulty in separating the mill-grits from the lower coal measures. The lower measures contain some thick and widely-spread sandstones, and the important coal seams, in some instances, rest on a hard ganister bed, and in others on a fire-clay. And to add to the similarity of the deposits of the upper grits and lower coal measures, marine fossils, such as species of goniatites, aviculopecten, and posidonomya, are intercalated above the coals. But the evidences of marine invasion ceased as the deposits accumulated, and more perfect terrestrial conditions arose. The Elland flag-stones, for instance, such prominent features to the west of this town and in the neighbourhood of Halifax, are fresh-water deposits, and are undoubtedly accumulated in an under-clay indicative of terrestrial conditions.

In the region north of the northern barrier successive coal seams and impure limestones and fire-clays occurred during the age of the depositions of the English grits, and then a thick fossiliferous sandstone was followed by the upper coals of Mid-Lothian.

All the minor upheavals and upsiltings of this long age were subordinate to a progressive general subsidence, in which the central and northern barriers were slightly implicated, and this extraordinary crust movement was to continue during the accumulation of over 3,000 feet of coal measures and other deposits, all subaërial in their method of formation, or having collected in shallow water or swampy ground. These products of denudation and of organism succeeded each other time after time; great gravels, shales, and sands were intercalated, and

even traces of some of the rivers of the age are to be found breaching the seams. The more the subject, commonplace as it may be thought, is considered, the more astonishing does it become, for the regularity of the subsidence and its amount must have kept pace with the thickness of the accumulating deposits. That there were many long intervals of quietude in the earth's crust may be gleaned, not only from the thickness of many coal seams, but also from the subaërial denudation which occurred. For instance, high up in the series in this district, is a mass of red sandstone which covers the denuded middle measures beneath; and this red rock of Rotherham, the result of coal measure denudation and removal, accumulated during the early days of the upper coal measures, for it is lower in the geological series than some members of the uppermost coal measures.

Before the close of the age, marine conditions occurred in the rock, and a limestone with goniatites was formed; but still coal seam formation proceeded until a totally different series of crust movements commenced in this country.

The flexures which were produced at the close of the carboniferous age had their long axes east and west; they suffered denudation and on the worn edges of their strata the "used-up carboniferous"—the lower Permian. Elsewhere, resting apparently and often really conformably on the carboniferous strata, the Permians accumulated until great north and south curvatures occurred and produced the Pennine chain.

The denudation of the anticlinal or upward curves of the north and south flexures progressed, and the coal measures, once continuous across England, were worn off along the back-bone of the country and from off the east and west ridges also. Vast as was the destruction and removal, there was still more compensation in nature, for faulting occurred on a large scale, and the measures were in many places sunken down below the level of possible subaërial denudation. It is to the pre- and post-Permian crust movements in producing basins and in uptilting the formerly horizontal seams, and to the subsequent faulting, that we owe the preservation and the possibility of reaching and working much of the coal of this country.

It appears that the position of this town refers quite as much to some remarkable faults, and the results of the post Permian uptilting, as to the presence of the river Don. Two important lines of fault run almost parallel, the one traversing the centre of Sheffield, and the other being to the north of the outcrop of the Silkstone coal. They pass in a north-easterly direction, and the country between them is much broken. Moreover, by a combination of the results of uptilt and faulting, the strike of important coal seams has been so altered that they encircle the town on the south, west, and north. The mineral products have thus been brought within the reach of those by whose industry this town has increased in size and population.

With regard to the lithology of some of the great series just mentioned, it may be suggested that the condition under which the beautiful limestones of the Avon, and the dark, shaly, muddy, calcareous deposits of the corresponding age accumulated in Scotland, were very different. The stone in the southern example is many coloured and is nearly an organic deposit, whilst the shaly strata of the northern series have crowds of calcareous fossils in them. Remove the shaly substance, however, and consider and compare the fossils of both localities, and no satisfactory distinction can be drawn between the depths at which they may have accumulated.

Both deposits contain crinoids, polyzoa, brachiopoda, and simple and compound hydro-corals. The same occur in the limestones to the north of the central barrier, which are intermediate in the arenaceous condition between those just mentioned. It is admitted that the mineral condition of the original deposits has altered, and it is possible that much impurity may have been removed by percolating carbonated waters, from the purest of the limestones. And, indeed, unless this is credited, it is impossible to compare some of these old marine sediments with any now forming on the floor of the sea. All the known calcareous sea floor deposits contain a very considerable percentage of silica and other matters, and if the carboniferous limestones were ever in the condition of modern deep-sea ooze, in order that they should have looked like the chalk they must have lost in some manner or other more than 35 per cent. of impurities. So far as I can understand, much of the carboniferous limestone may have accumulated at no very great depth and on banks within the scour of currents, and their prevalence would account for the comparative absence of sandy sediments in some situations. No traces of atoll formation exist.

With regard to one or two late discoveries relating to the organic remains of the carboniferous limestones, it is necessary to refer you to Moseley's important work amongst the Tabulata. These must now be removed from the true stony corals, and some will be relegated to the Hydrozoa, and others to the Alcyonaria. It is a fact of great interest that Sorby should have noticed that whilst the modern true corals are built up of carbonate of lime in the form of arragonite, the great tabulated forms of old are composed of calcite.

Quite lately Mr. Busk has been investigating the large polyzoa of the genus Heteropora, and I saw, under his manipulation, that this recent and Crag group, with strong palæozoic affinities, is so constructed that the branching tubular organisms of the oldest rocks with perforations in their walls and tabulæ must be included amongst species of genera closely allied to it.

A host of ill-defined tubular forms, such as the Stenoporæ, will thus find a final zoological resting-place.

The arenaceous series of the carboniferous formation in England are not less wonderful than the calcareous. They thin out very rapidly from 10,000 feet in the Burnley district to 100 close to the central barrier in Leicestershire, and it would appear that the sea drift was from the present region of the North Atlantic, along the shores of the swampy coal plant-growing-land.

The arenaceous deposits to the south of the central barrier have the same general relation as those to the north, and the grits of the Welsh and Bristol coal-fields are silicious, and were in all probability derived from the Silurian and old red rocks to their north-west. The culm measures of Somersetshire and Devonshire—those thick deposits with impure thin coals with limestones towards the bases—are of the age of the upper parts of the carboniferous limestones and of the grits of the central area. The evidences in this age of the denudation of granite and other silicious lands, and of more or less distant diffusion of the sediment, extend far and wide from the United Kingdom, a belt of similar rocks being found in south-western and central Europe. It is, moreover, very probable that the upper Vindhyan rocks of Hindostan, those fine sandstones and grits which have yielded the building-stones to the great Gangetic cities, are of the same relative age (or slightly older) as the strata of which so many Yorkshire towns are mainly built.

Whence came the thousands of feet of the sands and shales of the coal measures? is as yet a question which cannot be answered. It appears that very widely distributed deposits of the same kind are comparatively rare amongst them, and that most of the organic deposits, as well as the inorganic sedimentary, do not extend over great breadths, but are more or less lenticular in shape, or thin out or become changed in their lithology. This fact and Sorby's suggestion that the currents which deposited the strata had not any definite course rather tend to the belief in the former presence of a vast delta during that ancient aspect of nature. It is certain that some of the vegetation which subsequently became coal, and many feet of the roof above, were not always formed with great slowness, for stumps and trunks of trees have been found standing where they grew, with their roots in their under-clay and their stems wrapped round with coal, and the shale and gravel above. Moreover, in some places, a series of these interesting relics exists, one set being placed above the others.

With regard to the coal itself, varying as it does in its physical peculiarities, all that has an under-clay grew as vegetation on land. It is at present rather difficult to believe that where a coal-seam is found upon a hard silicious bed without a vestige of clay or of old soil, its plants were rooted there. But the stigmarian roots are not unfrequent in the ganister, and at the present time a peculiar vegetation is growing on the grits to the west of this town with a very small amount of humus intervening. Some coal-seams, especially the cannels, would appear, however, not to have been produced by plants which grew on the rocks beneath, and they are the result of vegetation drifting and becoming water-logged.

In reflecting upon the history of those carboniferous deposits in relation to the subsequent great changes in the physical geography of the earth, the idea that geological histories repeat themselves does not obtain that importance with which it is credited in relation to human events. It is true that there were important triassic, oolitic, wealden, neocomian, and tertiary lands, whose vegetation has been metamorphosed into a kind of coal. But the wonderful depth and the extraordinary vertical

repetition of organic and inorganic deposits, of the carboniferous formation, and the remarkable crust movements which enabled them to accumulate, are without subsequent examples.

In conclusion, I must remind you that the volumes of the "Geological Record" give the literature of the carboniferous formation year by year, and that lately a magnificent contribution to the subject has appeared in the memoirs of the Geological Survey of England and Wales in the form of a great volume on the geology of the Yorkshire coal fields, by Prof. Green, one of our vice-presidents, and Mr. Russell. A very concise and excellent geology of the West Riding has also recently been published by Mr. Davis, who is amongst us to-day, and Mr. Bauermann has contributed a capital article on coal to the "Encyclopædia Britannica."

THE FRENCH ASSOCIATION

Montpellier, Sunday

THE French Association for the Advancement of Science met at Montpellier on August 28. The president this year is M. Bardoux, the late Minister for Public Instruction, who has been succeeded by M. Ferry.

His address was devoted entirely to generalities on the necessity of providing a good education for the young. He did not touch upon the great question which agitates the public mind in France in connection with the Ferry Bill. It may be inferred from the strong encomiums passed on M. Jules Simon, that M. Bardoux must be ranked among the opponents to the Ferry Bill.

M. Laissac, mayor of Montpellier, and M. Cazelle, prefect of the Herault, replied to M. Bardoux. M. Saporta, the general secretary, gave an address summarising the results of the last year's meeting, and M. Georges Masson read a financial statement which showed that the capital of the Society amounts to about 300,000 francs. The subsidies paid for research last year amounted to 10,000 francs.

These addresses being the only ones which were given in the name of the Association, and as the presidents of sections gave no official addresses, it will be quite impossible to have any idea of the opinions of the meeting on the topics of the day.

Although but a small city, Montpellier is famous in the annals of science, and in former years its university was deemed a rival to Paris. But in latter years Montpellier has lost much of its *prestige*, although it had the honour to be the birthplace of Auguste Comte. The growing academy of Toulouse disputes with Montpellier the pre-eminence in south-eastern France. Meanwhile the impending meeting of *savants* at Perpignan on the occasion of the inauguration of Arago's statue at the end of September will throw the Montpellier meeting somewhat into the shade, and deprive it of a number of constant and influential members. The interest of the meeting will consist principally in excursions professing to promote ends of great moment for the welfare of the region, viz., the extinction of phylloxera, the construction of an irrigation canal from the Rhone, the local meteorology and botany, which are strongly represented by M. Charles Martins, a brilliant writer, and the director of the celebrated Montpellier plant-gardens. A specimen of the French Atlantic cable now in course of being placed, will be exhibited and explained by M. Gariel, the general secretary of the Council, and the scheme of the French Company explained for the first time. Experiments will be made on electric lighting and the telephone.

The French scientific caravan, officered by MM. Quatrefages, Mortillet, and Broca, to be sent to the Congress of Anthropology at Moscow, is to arrive in Montpellier before the end of the meeting. M. Bergeron, one of the French *savants*, who was present at the Sheffield meeting, has arrived in order to tell the French Association of what was done by her elder sister.

THE SWISS NATURALISTS

THE sixty-second annual meeting of the Swiss naturalists was opened on July 10 at St. Gall. The attendance was comparatively large, no less than two hundred Swiss and twenty-one foreign *savants* being present. Among the latter we notice Prof. Hébert (Paris), Mr. Forrer (San Francisco), Herr Nördlinger (Stuttgart), Dr. Richthofen, and many others.

On Monday, the 11th, the first public meeting was opened at the Grossrathhaus, before a large audience of visitors and ladies, by Dr. Rechsteiner (St. Gall), who gave an address on the recent progress of science; also pointing out the importance of the neighbourhood of St. Gall for the study of geology, and discussing the variety and importance of chemical processes in the life of nature. A second lecture was given by Prof. C. Vogt (Geneva) on the archæopteryx, the interesting reptile-bird which has provoked so animated a discussion among anatomists, and of which we possess only two specimens—that of the British Museum and that newly discovered at Solenhofen, Germany. According to the first, which was very incomplete, this Jurassic animal was considered as a bird, having a beak, nails, and feathers; while the Solenhofen specimen, quite complete, and of which Prof. Vogt exhibited very good photographs, proves undoubtedly that we have to do with a bird-like reptile of the size of a pigeon, which had both scales and feathers, a beak provided with teeth, armed wings, bird-like feet with nails, and a reptile tail consisting of twenty vertebræ. This discovery gave to Prof. Vogt the occasion to make a brilliant address on the origin of species, the adaptation of organisms to the medium they inhabit, and the way in which this adaptation goes on from the periphery to the centre.

Two other lectures were given by M. Victor Fatio, on the phylloxera, and by M. Raoul Pictet on the synthetical theory of calorific phenomena. The naturalists then went to the traditional breakfast served on paper table-cloths with paper napkins, in the beautiful hall of the Kornhalle, the walls of which are decorated with four pictures, by M. Kirchofer, which represent the country of St. Gall during the periods of the lignite (*Schieferkohle*), of the molasse, of the glacial epoch, and of prehistoric man. At two began the sittings of the sections. In the Section of Physics Prof. Hagenbach opened a very interesting philosophical discussion on "centrifugal force," in which discussion he was followed by Prof. Mousson (Zurich), who made a valuable communication on the structure of solid bodies, and on the molecular phenomena which produce the phenomenon of heat. Prof. Pictet (Geneva) explained his researches into the mechanical theory of heat. On the following day Professors Forel (Morges) and L. Soret (Geneva), the indefatigable students of the oscillations of the level of the Lake of Geneva, gave, in the Section of Physics, very interesting communications on that subject, and especially on the rhythmical oscillations described as *seiches*.—M. Dufour having communicated the results of his measurements on the glacier of the Rhone, according to which the lower extremity of this glacier has receded no less than eighty metres (260 feet) during the last two years, a long discussion on the causes of the oscillations of glaciers was engaged between MM. Dufour, Forel, Mousson, and Hagenbach. Finally we notice in the Section of Physics the communications, by M. H. Dufour, on the diffusion of gases; by Prof. Hagenbach on the forms of hail; and by Prof. Colladon (Geneva) on his theories on the optical properties of ice.

The sixty-third meeting will take place next year at Brieg, in the Valley of the Rhone.

SCIENTIFIC SERIALS

The Journal of Physiology (vol. ii. No. 2, issued July).—On the effect of the respiratory movements on the pulmonary circulation, by H. P. Bowditch and G. M. Garland.—On absorption without circulation, by B. F. Lautenbach.—On protagon, by Arthur Gamgee and Ernst Blankenhorn.—On a few further experiments with pituria, by Sydney Ringer and William Murrell.—On the antagonism between pilocarpine and extract of *Amanita muscaria*, by Sydney Ringer and William Murrell.—On some old and new experiments on the fibrin-ferment, by Arthur Gamgee.—On the effect of two succeeding stimuli upon muscular contraction, by Henry Sewall.—There is added a list of titles of books and papers of physiological interest published since December 31, 1878, to date.

Journal of the Royal Microscopical Society (August).—Transactions.—On a new species of excavating sponge (*Alectona millari*), and on a new species of Raphidothecea (*R. affinis*), by H. J. Carter, F.R.S.—On a new genus and species of foraminifera (*Aphrosina informis*), and on the spicules of an unknown sponge, by H. J. Carter, F.R.S.—On the theory of illuminating apparatus employed with the microscope, by Dr. H. E. Fripp.—Observations on *Notommata Werneckii* and its parasitism in the tubes of Vaucheria, by Prof. Balbiani; translated from the *Annales des Sciences Naturelles* (*Zoologie*), 1878.—The record of current researches relating to invertebrata, cryptogamia, microscopy, &c.

The American Naturalist (August).—Adjectives of colour in Indian languages, by Albert S. Gatschet.—On the habits of a species of tarantula (*T. tigrina*?), by Mrs. Mary Treat.—On the formation of Cape Cod, by Warren Upham.—The geological museum of the School of Mines, Columbia College, by Israël C. Russell.

Kosmos, iii. Heft 3, June; Th. Buy, on the estimating of conflicting authorities, or thoughts on the education of the future.—Dr. Otto Kuntze, how the primitive rocks are built-up.—Dr. Dodel-Port, Infusoria as assisting in the fructification in the Florideæ, being a contribution to our knowledge of the interchange of relations between the plant and animal worlds, with illustrations.—Dr. D. F. Weinland, on the statistics of population in the animal kingdom.—T. H. Becker, on the serpent myth.

THE *Revue Internationale des Sciences* (August) contains the following papers:—On the embryogenous vesicle and on parthenogenesis in animals, by Prof. Balbiani.—On the metaphysics of Claude Bernard, by Ch. Letourneau.—On the history of embryological doctrines, by Prof. Kölliker. This is the recapitulation of a German work by the eminent biologist, recently published in a French translation.—On the reality of our perceptions, by Prof. Helmholtz.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, August 18.—M. Daubrée in the chair.—The following papers were read:—On the meridian observations of the minor planets, made at Greenwich and Paris during the second quarter of 1879, by M. Mouchez.—Mr. J. A. Serret presented to the Academy the eighth volume of the works of Lagrange, entitled "Traité de la Resolution des Equations numériques de tous les Degrés, avec des Notes sur plusieurs Points de la Théorie des Equations algébriques."—M. Milne-Edwards presented the complement of the thirteenth volume of his "Leçons sur la Physiologie et l'Anatomie comparées de l'Homme et des Animaux."—Reply by M. Berthelot to M. Wurtz's observations on hydrate of chloral.—On the phenomena of secreting irritation which are apparent in rabbits under the influence of faradisation of the tympanum, by MM. Vulpian and Journiac.—Table of numbers of invariant derivatives of given order and degree, belonging to the binary form of the second order, by Prof. Sylvester.—Methods of graphic calculus; employment of these methods for the revision of projects bearing on the development of the network of French railways, by M. L. Lalanne.—On irrigations and the sulphide of carbon, by M. Mabègue.—On the submersion of vines as a remedy against phylloxera, by M. Faucon.—M. Davin made a communication on the same subject.—The President then stated to the meeting that M. Janssen had been designated to represent the Academy at the inauguration of the statue of François Arago at Perpignan.—The second volume of the "Correspondance politique de Frédéric le Grand" was presented to the Academy by the Berlin Academy of Sciences.—On the integration of irrationals of the second degree, by M. Alexéeff.—Observations on M. Aoust's note on the movement of a straight line in a plane, by M. Ed. Habich.—On atmospheric waves and the monthly lunar equation, by M. Bouquet de la Grye.—On the scintillation of coal-gas flames, by M. F. A. Forel.—On the absorption of nitric oxide by the proto-salts of iron.—On the reaction of chloride of zinc on normal butylic alcohol, by MM. Le Bel and Greene.—Thermal researches on nitroglycerine, by M. H. Boutmy.—On the tenor of urea in urines, by M. G. Esbach.—On the elimination of bromine from bromocitraconic acid, and on a new organic acid, by M. E. Bourgoin.—On scandium, by M. P. Clève.—On the oxy-acids of sulphur, by M. Maumené.—On the composition of slate, by the same.—Note on a means of preventing inundations, by M. A. Sarrand.—On a peculiarity apparent in Jupiter and its satellites, by M. E. Gand.

August 25.—M. Daubrée in the chair.—The following papers were read:—Discovery of two comets, communicated by M. Mouchez. One was discovered by M. Palisa, of Pola, and the other by M. Hartwig, of Strassburg.—On the digestive ferment of *Carica papaya*, by MM. Wurtz and Bouchut. This strong ferment (*papaïne*) is easily isolated.—Reply to M. Berthelot's observations, by M. Wurtz.—On a process by which may be obtained in any ball-governor, the degree of isochronism desired, and maintaining this degree for all speeds; general theory, by M. Léauté.—On some multiple stars, according to observations made at the Imperial Observatory of Rio de Janeiro, by M. Cruls.—Researches on the compressibility of gases at high pressures, by M. Amagat. All the gases studied, except hydrogen, presented a minimum of the product pv, situated for each gas about the following pressures (expressed in metres of mercury): nitrogen 50 m., oxygen 100, air 65, carbonic oxide 50, formene 120, and ethylene 65. Thus, as might be expected, the gases that are probably nearest the circumstances determining their liquefaction are those which attain the greatest compressibility.—On the maximum tension and the vapour density of alizarine, by M. Troost. The maximum tension is about 11 mm. at 261° and 20 mm. at 276°. The observed density was, in three experiments, 16·32, 15·0, and 17·8. (The formula $C_{28}H_8O_8$ leads to the calculated density 16·62 for 4 vols. The equivalent of alizarine, then, corresponds to 4 vols.).—Purification of hydrogen, by M. Lionet. This may be effected in the cold state. Oxide of copper arrests, in cold, all the combinations of hydrogen which it may contain as impurities, except carbonised hydrogens.—On the active principle of *Ammi visnaga*, by M. Mustapha.—On a new mode of administration of ether, chloroform, or chloral to the sensitive plant; application to determining the velocity of liquids in the organs of this plant, by M. Arloing. The mode is that of presenting the anæsthetic to be absorbed by the roots. Chloral does not act as an anæsthetic on the sensitive plant; the other two have a similar action to that on animals whether they penetrate by the leaves or the roots. The petioles fall suddenly and successively from below upwards as chloroform absorbed by the roots reaches their insertion. Hence the rate of absorption can be easily calculated. The velocity increases from the base to the top and is one and a half times to twice as great in the petioles as in the stem.—Studies on hydrophobia, by M. Galtler. This relates chiefly on its manifestation in the rabbit, to which it may be transmitted, causing paralysis and convulsions. Salicylic acid administered by hypodermic injection daily did not prevent development of the disorder in the rabbit. The saliva of a mad dog, obtained from the living animal and preserved in water, is virulent, in some cases, even twenty-four hours afterwards.—Researches on animal heat, by M. D'Arsonval. Calorimetry should, scientifically, precede thermometry. The author proposes a new calorimetric method, by which the production of heat in animals can be followed during whole days and weeks. The calorimeter is in an inclosure at constant temperature; and it regulates automatically its own temperature, which remains always invariable.—Researches on the *rôle* of nerve fibres contained in the anastomosis between the superior laryngeal nerve and the recurrent laryngeal nerve, by M. François Franck.—On the malacodermic zoantharia of the coast of Marseilles, by M. Jourdan.—Diffusion of copper in primordial rocks and sedimentary deposits proceeding from them; consequences, by M. Dieulafait.—The falling stars of August, 1879, by M. Chapelas.

CONTENTS

THURSDAY, SEPTEMBER 11, 1879

OUR NEW PROTECTORATE

Our New Protectorate, Turkey in Asia; its Geography, Races, Resources, and Government. By J. Carlile McCoan. 2 vols. (London: Chapman and Hall, 1879.)

Narrative of a Journey through Khorassan and on the North-west Frontier of Afghanistan in 1875. By Col. C. M. MacGregor, C.S.I. Bengal Staff Corps. 2 vols. (London: Allen and Co., 1879.)

WHATEVER other interests may have suffered through the late convulsions in the East, those of science, and especially of geography, have at all events been largely benefited. The cession of Cyprus to England and the Anglo-Turkish Convention, which brings a large part of Western Asia within the British political system, could not fail to direct general attention to those regions, thus giving occasion to a number of more or less comprehensive treatises on their physical conditions, natural resources, ethnical, social, and political relations. Of these works, those whose titles are here given, while differing widely in their scope and treatment, are each in its way very favourable specimens. Of the two, that of Mr. McCoan is perhaps on the whole the most satisfactory, as from its purpose and nature it is likely to prove of the greatest permanent interest. Within the compass of two moderately-sized octavo volumes it deals with an immense variety of topics. Yet such is its admirable arrangement, and so thoroughly master is the writer of his subject, that there is nowhere any crowding or confusion, and the result is a most convenient and reliable handbook of "Our New Protectorate." Nothing is omitted that comes fairly within the scope of such a treatise, and a twenty years' personal experience of an intelligent observer of men and things will be sufficient guarantee of the accuracy of his statements, if not always of the justness of his conclusions. In the first volume separate chapters are devoted to each of the five great divisions of Asiatic Turkey, whose orography, hydrography, climate, natural products, present economical conditions, trade routes, political divisions, are treated in detail. These are followed by more comprehensive chapters on the history, races, religions, resources, and government of this eastern section of the empire. The second volume is occupied chiefly with questions of an economical and social character—public works, public instruction, trade centres, agriculture, slavery, polygamy, the Ulema, the capitulations, abuses, necessary reforms.

The chapters on natural resources, products, and agriculture, convey a vivid picture of the inexhaustible latent wealth of these regions.

"On both sides of the Bosphorus Nature has fitted Turkey to be a great agricultural country, but in Asia the geological and climatic conditions of successful husbandry combine in a degree seldom equalled in Europe. Hence nearly every kind of agricultural produce known to commerce may be raised on a scale of abundance limited only by the labour and intelligence employed. The present condition of the country, it need hardly be said, supplies no measure of its full capabilities, but even as it is, the merest bird's-eye glance at its chief products, under all the existing disadvantages of gross fiscal abuses, the most primitive rudeness of culture, and the want of outlets for everything grown beyond the actual needs of local consumption, will show how rich and wide is the field awaiting only better government and a moderate infusion of western skill and capital to become again one of the most productive in the world" (vol. i. p. 203). Nothing, perhaps, gives a better idea of the immense variety of these products, than a glance at the export trade of Smyrna, including, as it does, such varied items as rice, maize, and other cereals, opium, tobacco, silk, and cocoons, valonea, madder, gall nuts, yellow berries, mohair, sponges, besides large quantities of dried figs and raisins of prime quality.

Yet, boundless as they are, these surface-products are represented as scarcely exceeding in importance the vast mineral treasures that lie still almost untouched in the bowels of the earth. "The soil of Anatolia, especially, is largely composed of those earlier rocks which are known to be the most rich in minerals, rocks, in fact, to which some of the most valuable of these are altogether confined. The country is said, indeed, to possess almost every sort of metal except platina. Not only, too, are most of the mineral districts near either the sea or navigable rivers, but—what is even of more importance—the metallic and carboniferous beds are found close to, or within practical distance of, each other. We have thus, in many instances, the proximity of coal and iron which has made the fortune of Staffordshire, and the absence of which in Spain has rendered the rich mines of the Asturias nearly valueless. According to the official records of the Porte, in all some 250 mines of various ores have been discovered throughout the Empire, three-fourths of which are in Asia. Most of these latter were formerly worked, but the great majority have been abandoned through want of capital or for other reasons, leaving only about thirty now at work, and not one of these to the full limit of its producing capacity" (vol. i. p. 209). Detailed accounts are given of some of the more valuable of these deposits, including the famous coal-fields of Erekli, which form part of the Sultan's private domain, but which are so badly worked as to be almost unremunerative.

The rival schemes of railway communication through Turkey with India are briefly but clearly explained, and their merits impartially balanced. In the large map of Turkey in Asia accompanying the work the several routes are laid down, together with the proposed extensions, and all the highways actually completed. In future editions this map might be advantageously supplemented by another, showing the administrative divisions, vilayets, sanjaks, kazas, which are so necessary to a full comprehension of Turkish geography, and which are yet so difficult to procure.

Col. MacGregor's work appears somewhat late in the field, but is none the less welcome as a valuable contribution to our knowledge of a region still but little known, notwithstanding its daily increasing political importance. It is somewhat of the nature of an itinerary, in which the towns, distances, elevations, water and mountain systems, and all other points of interest along the route traversed by the enterprising explorer are carefully described. From the title it might be supposed that the ground thus sur-

veyed was restricted to the provincc of Khorassan. But the whole of the Iranian table-land was actually crossed from Bushire, on the Persian Gulf, through Shiraz and Yezd, in a north-easterly direction, to the Afghan frontier. Here it was the traveller's intention to break fresh ground by penetrating from Herat along the Hari-rud valley, and through Bamian, direct to Kabul. But this scheme, which would have opened up an entirely new region, was thwarted at the outset by two insurmountable difficulties.

The immediate consequence was that instead of an able and much-needed work on the Perso-Afghan highlands, we have one limited mainly to the north-eastern districts of Persia. On this region much additional light is thrown, and an attempt is made to remove the obscurity still attaching to the water-system of the country between the Bakharz and Ghaïn ranges. "The drainage of the space between the northern face of the Doroh hills, the eastern slope of the Ghaïn range, and the southern side of the Khaf range, I believe to be as follows:—First, it does not enter the Hari-rud by the Karat-rud, cutting the Dushakh ridge, as is shown in our maps, nor does it drain to the Harût-rud, or to the Hari-rud direct. All the drainage of this space is absorbed into three great depressions, called 'daks,' that is, the drainage of Nibolûk, of Ghaïn, and of Khaf Païns, goes to the Dak-i-Diwalan; that of the Zirkoh tract, which includes all to the east of the Auguran range, including Gulwarden, Yezdun, and Kaland, drains into the Dak-i-Khurshab, close to the Koh Kabuda; while that of Fûrg, Daramian, Ahwaz, &c., drains to the Dak-i-Tundi, fifteen farsakhs from Ahwaz, and a portion from Mogulbackhe to Pahre runs direct into the Hari-rud. This may seem at first sight a rather startling statement, but it is not so in reality. In the first place, it must be remembered that the process of denudation of the surrounding hills, which is constantly going on, must have a tendency to create the low ridges which cause these depressions; and as there is not sufficient water to keep a way open for itself, and, moreover, the soil is salt, what there is is rapidly evaporated and sucked in, and it is easy to see how these drainage beds have lost the power of discharging themselves to what, no doubt, should be their proper exit, the Hari-rud" (vol. i. p. 204).

Elsewhere some useful information is given regarding the "kavirs," "rîgs," "lûts," and "beyabûns," which occupy such a large portion of the Iranian tableland; but the existence is denied of one continuous "kavir" (salt desert) stretching from Kûm to Bejistûn, though "there are a great number of smaller kavirs due to local drainage"[1] (vol. ii. p. 138). A graphic description is given at p. 101, vol. i., of one of these dreary kavirs twelve miles long on the route between Kûr and Tabaz. "It is rather difficult to suggest anything that will give an English reader an idea of what this kavir is. It is not sand, nor is it in the least like the desolate plains of India, which, burnt up as they may be, are luxuriant in their vegetation compared with kavir. It has, speaking quite literally, not one blade of grass, nor one leaf of any kind, not a living thing of any sort. It is composed of dark soil, which looks as if it had been turned up by the plough a year before, but which is covered with a thick salt efflorescence, which glitters painfully to the eyes. All round, as far as the eye can reach, there is nothing to be seen but this glare of white, which seems to stare piteously on you as you pass by, crunching over its dry crust. Every here and there is a dark patch, which, on getting up to, you find to consist of moist earth which seems, as it were, to have sweated up from beneath. These patches also dry up, and then the salt shows. The surface of the kavir is not smooth, but is so honeycombed with small holes about nine inches deep and the size of a man's head, that it is very difficult walking for animals; but as the soil of the kavir binds very well, a good road could doubtless be made over it."

Altogether, what with kavirs, stony wastes, rough roads, brackish water, filthy serais with little accommodation beyond foul air and noxious vermin, it is not astonishing to learn that the writer did not find travelling in Persia much more pleasant than others have done before him, and it is depressing to hear that there is little prospect ot any improvement in the future. "The worst of this country is that, bad as it is, one cannot conceive how it could be improved in any single way. There is no water, it produces absolutely nothing, and there is no possibility of water being collected for irrigation" (vol. i. p. 84). Worse still, the sands are in many places visibly gaining on the arable land, and even on the inclosed cities themselves. "The country is, in fact, in the process of changing from a series of rocky ridges to one of undulating sandy wastes. Yesterday's march showed the sand triumphant; to-day the rocks are still fighting on. This process of burying is most peculiar, and may be witnessed on a small scale in almost any village between this and Yezd. You see the sand blown against the wall, gradually getting higher and higher, till it blows over and then forms a mound in the field beyond, which gradually increases its height till all trace of wall and field is lost, and you have before you a sand-heap. I can quite believe now the stories of towns being buried, having myself seen the thing on a small scale" (vol. i. p. 147).

In the caravanserai of Bandar Gaz on the Caspian, acquaintance was made with what would appear to be "a new specimen," which may interest entomologists. "It had a head all made up of eyes, a body like an ordinary fly, and a tail like a gimlet. It never made any noise, and it always attacked to the rear, and once it had got its gimlet into you, it seemed to afford it such pleasure that it invariably parted with its life sooner than let go. But its effects were not realised till after death; then came on an itching pain that nearly drove one mad" (vol. ii. p. 166).

In case a second edition should be required of this work, attention may be directed to the peculiar spelling of proper names, with a view to introducing some kind of law and order where all is now sheer chaos. It would probably be too much to hope for a uniform adherence to some scientific or at least intelligent system of transliteration; but a moderate degree of consistency might at least be expected from a writer who has some knowledge of the Arabo-Persian writing system. But here we have neither consistency, nor uniformity, nor anything but the wildest confusion, and the accompanying map at

[1] Originally *kavir*, or rather *kabîr*, was an adjective, simply meaning *great*, the full expression being *Darya-i-kabîr*, "the great ocean," *i.e.*, of salt, and it may be added that, notwithstanding Col. MacGregor's view, the natives invariably apply this expression collectively to the whole of the vast region stretching from the Ghaïn highlands westwards to Yezd and Kashan. Further north this salt waste would seem to intersect the Ghaïn range west and east, here merging with tbe Khaf Desert, which joins the Dashti Na-ummed "desert of despair") on the south, and the Ghorian wastes on the east.

variance with the text, the text with itself. Hence, to quote a few out of innumerable instances, such alternatives as Yezd and Yuzd, Dalaki and Dulukee, Mahamadan and Mahomedan, Geeach and Giach, Tabaz and Tubbuz, Ghain and Ghaeen. Then such old friends as Meshed, Bushire, Turcoman, Hari-rud, disguised as Mushud, Bushuhr, Turkmun, Hurri Rood, without any conceivable advantage. It may be stated that owing to these eccentricities the spelling in the passages here quoted has necessarily been reduced to system.

A. H. KEANE

OUR BOOK SHELF

Catechism of Agricultural Chemistry and Geology. By the late J. F. W. Johnston. An Entirely New Edition, Revised and Enlarged by C. A. Cameron, M.D. Seventy-eighth Thousand. (Edinburgh and London: Blackwoods, 1879.)

THIS popular and useful little book has been decidedly improved by the additions and alterations which Dr. Cameron has made. Since the author's death, about a quarter of a century ago, this catechism had been once revised (in 1863) by Dr. Voelcker, but the time had long since arrived for further changes. If the present editor had been less scrupulous in adhering to the original form and substance of Prof. Johnston's work, this issue would have justly merited the description on the title-page of "An entirely new edition, revised and enlarged." There are, it is true, two fresh pages in the present edition, corresponding to a few new tables of the composition of cattle foods, but we fail to find the numberless small changes and additions which the progress of science demanded. Every sentence of the book should have been rigorously scrutinised and thoroughly amended, or even excised, where necessary. All expressions such as these: "Rancid butter is said to be sweetened" (p. 73), "It is said that if a cow be liberally supplied with whey" (p. 74), "The feeding with whey thickened with meal is said" (p. 74), should be removed. Statements of which the teacher is not sure should not find a place in an elementary catechism. Again, the table, on p. 34, of the ash-constituents removed from an acre by various crops needs emendation. On turning to page 53 we find two other tables showing the produce of corn and straw in certain field experiments with various manures. We do not think the omission of these tables would entail any loss, while their place might be profitably occupied by a series of conclusions deduced from the really satisfactory experiments on crops made at Rothamsted or at some of the continental agricultural stations. For, indeed, what lesson can be learnt from the statement (p. 53) that in an unnamed locality, on an undescribed soil, during a season of which the rainfall and temperature are unrecorded, and by the use of a wheat manure the composition of which is not furnished to the reader, 42 bushels of wheat were produced per acre? Without duplicates and without repetition in different localities and in different seasons, field-trials of manures are positively misleading. But when once such tables as those on pages 34 and 53 have got into a popular work and remained there fifteen years, they have a good chance of remaining fifty.

The statement on p. 67 that parsnips contain no starch will not stand, while we conclude that it was by some oversight that a tabular account of the constituents of various root-crops has been omitted by Dr. Cameron in re-casting and amplifying the data given by Dr. Voelcker in previous editions on page 65. We note here that question 363 on page 63 is repeated in question 374 on page 67, and that the statistics (p. 74) of cheese production in the United Kingdom are no longer correct.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

Palisa's Comet

I INCLOSE an ephemeris of the comet which was discovered at Pola by Herr Palisa on August 21, thinking that it may be of interest to some of your readers.

The ephemeris is calculated from observations made at my observatory on the nights of August 26, 27, and 28, by Dr. R. Copeland and Herr Lohse.

The comet is easily visible in a 4-inch telescope.

Insect Swarms

IT may be worth mentioning in connection with Mr. J. Clarke Hawkshaw's interesting account of the wonderful insect-swarm at Trouville, on August 12 and 13, that the two species which composed it were noticed in immense profusion about the same time in the West of England.

On the 13th ult. (which was one of the very few summer days of the season) I was driving with a friend from Exmouth to Budleigh-Salterton, on the South Devon coast, when our attention was attracted by the enormous multitude of insects (moths and butterflies) which were fluttering over the flowery margin of the road. The butterfly was at once recognised as the "Painted Lady;" the moth was not determined, but from its general appearance, its companionship, and all the circumstances of the case, I have no doubt that it was the *Plusia gamma*. The swarm attended us, with little variation in the numbers, throughout almost the whole of our journey (a distance of five miles), and on reaching Budleigh we found *V. cardui* clustering thickly on the flowers in the brilliant little gardens facing the sea.

Along the road the moth was in the greatest profusion, the numbers being frequently so great as to form a perfect *cloud*.

The effect of the quick, restless, irregular movements of the great host, stretching on mile after mile, was very curious. The butterflies were, of course, less plentiful, but still their numbers must have been immense. They seemed to be finely coloured and in very perfect condition.

The direction in which the swarm was travelling was not specially noted; indeed if food was the object sought it might

well be content to linger in the rich and pleasant pasturage in which we encountered it.

I may add that our observations were confined almost entirely to the grassy and flowery borders of the road, and that the swarm which excited our wonder was probably only a single column of a countless host. THOMAS HINCKS

Budleigh-Salterton, September 2

"Rag-Bushes"[1]

A REMARKABLE instance of this custom existed (I am referring to twenty-five years ago) in Ceylon. On the West Coast, on the road between Chilaw and Jaffna, at a place—the name of which, after so many years' absence, I forget—was a vast collection of rag-offerings suspended to the bushes through which the road was cut. It went by the name of "Rag Fair," with those of us who had travelled in that direction: there were miles of it. They were said to be offerings to the goddess "Kali" (who, in the midst of them, had a temple and *well*), to propitiate her and obtain her protection against the dangers of the way, especially those of wild beasts.

Once travelling up that road, my horsekeeper, "Multu," watered my horse at the sacred well. Out rushed the priest, furious with wrath, and cursed Multu with all the vengeance of "Kali," assuring him that he would be eaten by leopards that very night.

Multu, who, I fear, was an atheist after his kind, merely laughed at the offended guardian of the shrine, and pointing to my rifle lying in the hollow of his arm, told him that while the master or himself carried *that*, he did not care a copper "chailly" (a "brass farden," vernacular) for "Kali," the leopards, or himself.

I soothed the irate old humbug by hanging a strip of rag, which I carried in my pocket for gun-cleaning, on a branch, but especially with a trifling bit of silver—I believe this latter portion of an offering is usually, with miracle- and charm-makers, the most efficacious—and went my way.

Multu had his triumph that night. A wretched coolie travelling along the road—one of the class that supply the chief abundance of the rags—after hanging up his offering and doing "pooja," was, while sleeping in the "maddam," or porch of the temple, of his protecting goddess, actually seized and carried off by a leopard. He was rescued—how, I forget—and brought to the "Rest-house" where I was, but was so dreadfully lacerated about the hips and lower portion of the body that he died in a few hours. E. LAYARD

British Consulate, Noumea, July 5

Signalling by Sunshine[2]

THOUGH I fear by the time this reaches you the subject will have been exhausted, I send you this "note;" you can but throw it into the paper-basket if not wanted.

While at the Cape of Good Hope, my dear old friend Sir Thomas Maclear, then Astronomer-Royal, told me that while measuring the arc of the meridian to verify Lacaille's work, he signalled with the heliostat enormous distances, the clear atmosphere of the Cape being eminently adapted for the purpose. If my memory does not play me false, I think he said one station in connection with his cairn on the top of Table Mountain (3,800 feet) was ninety-five miles distant.[3]

His means of directing the flash was as follows:—A tiny hole is scratched in the quicksilver in the centre of the heliostat, and a board with a larger hole is planted in front of the station, some few feet from the instrument.

The corresponding station is brought in view through the two holes, and all three are consequently "in line." The flash is then directed through the hole in the board, and is thus sent straight to the desired point. Of course telescopes were used for long distances.

Another old friend, Admiral Trotter, used to converse from Admiralty House, Simon's Bay, with friends staying at "Kalk" Bay, some eight or nine miles distant. E. L. LAYARD

British Consulate, Noumea, July 4

[1] NATURE, vol. xx. p. 595. [2] NATURE, vol. xx. p. 508.

[3] An amusing coincidence may be noted here. I was returning from Graham's Town by a steamer, and when we came in sight of the old mountain, I happened to mention Sir Thomas's signalling. My hearers on board jeered at the possibility of making signals with "a piece of looking-glass," when suddenly we were half blinded by a flash of light from the top of the mountain. "What on earth is that?" was the general exclamation! "Only Sir Thomas signalling," was my triumphant reply, "Perhaps you will some of you now believe in a 'bit of looking-glass.'" Sir Thomas' son had, for fun, sent a flash or two down to the steamer.

Bag-like Fabrication exhibited by Sir Sydney Saunders

As much the "production of a large species of spider in Fiji" as a lady's silk dress is the "production" of a worm in China!

A large spider, of a genus common all over Polynesia, and here also in New Caledonia (where formerly much eaten by the aborigines) produces a very strong, thick web. On Sundays generally, when no work is going on in the plantations, the imported Pacific Islanders amuse themselves by wandering about the bush, armed with a frame-work of cane in the shape of an elongated cone, affixed to a long stick. This they twist and twist, round and round in the spiders' webs, till it is coated, sometimes half an inch thick, with the viscous fabric. They then untie the fastenings and draw out the strips of cane, when the bag becomes like a long night-cap (old pattern). I have one before me now, over a yard long, a foot across, and pretty thick, which does not weigh one ounce! It is yellow; the New Caledonian ones are usually grey. I do not think the Fijian natives had the custom originally. Some of the New Caledonian are stretched tight enough to resemble an Indian suspension "tom-tom," and really emit a slight sound on being "tapped." This will give some idea of the strength of the thread, for which see also *The Field* ("My Trip to Lifu"), wherein I notice the impromptu butterfly nets made by some boys stretching the web of this spider across the loop of a bent twig. Observations on a Wind-Whirl

WHILE making magnetic determinations at Schell City, Mo., a wind-whirl of some violence passed near our tent, moving with the characteristic swaying and halting motions of the tornado. Its base was quite pointed, and about two feet in diameter.

Unlike those seen last year, and described in NATURE about a year ago, there were no surface-winds strong enough to bear dust along the suface of the ground, but the dust carried up in the vortex was collected only at the vertex of the whirl. The dust column was about 200 feet high, and perhaps 30 or 40 feet feet in diameter at the top. The direction of rotation was the same as that of storms in the northern hemisphere. Leaving the road, the whirl passed out on the prairie, immediately filling the air with hay, which was carried up in somewhat wider spirals, the diameter of the cone thus filled with hay being about 150 feet at the top. It was then observed, also, that the dust column was *hollow*. Standing nearly under it, the bottom of the dust column appeared like an annulus of dust surrounding a circular area of perfectly clear air. This area grew larger as the dust was raised higher, being about 15 or 20 feet wide when it was last observed. This whirl could be observed half a mile, finally disappearing over a hill.

This observation, in connection with the one given by me a year ago, has a very important bearing on the theory of "waterspouts" and tornadoes. FRANCIS E. NIPHER

St. Louis, Mo.

Transportation of Seeds

IN a recent number of NATURE which has lately reached my hands, I observe a letter from Consul Layard on the above subject, to which let this note be an addendum.

In my daily expeditions I am exceedingly troubled by the seeds of the *Andropogon acicularis* (Retz), not only adhering on the slightest touch to my clothes, especially to my trousers and socks, to the daily annoyance and occupation of much of the time of my servant in their obstinate removal, but even penetrating my limbs and adhering there to my great discomfort, for the itching that they cause is sometimes intolerable; and my limbs consequently present somewhat the appearance of those of a scarlet-fever patient. HENRY O. FORBES

Kesala, Bantam, Java, July

Shark's Teeth

I WOULD draw attention to the operation of the teeth of the shark on the seizure of its prey. I recollect in Nicholson's "Zoology," a statement to the following effect: "The sharks have teeth arranged in several rows, of which only the outermost is employed, the other rows seeming to replace the outermost when worn out." In a recent visit to the Cocos Islands I had many opportunities of observing these animals in the use of their formidable weapons. In the act of seizure the whole jaw is protruded to a distance (varying according to the size of the fish) of several inches, the innermost teeth coming into position erect

or semi-erect, but as far as I could observe nearly *all* the teeth came into play. When on fishing excursions in the lagoon, the sharks which constantly carried off the bait, were often caught, and in order to extract the hook, a large log, constantly carried in the boats for this purpose, was threateningly presented to its face, and of course instantly seized and held on to for as long as it took to perform the operation of extraction. If, when the fish is quite recently dead, pressure be made on the angle of the jaw, it is easy to observe the action of the rows of teeth.

Kesala, Bantam, Java, July HENRY O. FORBES

A Lunar Rainbow

LAST evening, September 3, at 10.40, a lunar rainbow was visible at Llanfairfechan, in a north-west direction. The arc was continuous, and of a brilliant white light. It appeared to stretch across Anglesey from Beaumaris to Puffin Island. The bow did not last more than 2′ from the time it was first observed by us. F. E. KITCHENER

Llanfairfechan, September 4

A Habit of Cattle

IN the colony of Natal the cattle have an extraordinary liking for bones. They will stand for hours with a bone in the mouth quietly munching, sucking, or perhaps more correctly speaking, levigating the bone with the tongue. I have not heard that cattle have the same habit in the other colonies of South Africa, but I have been told that cattle exhibit the same taste in some parts of South Australia.

In Natal there is, I believe, a scarcity of chalk and limestone in the geological formation. Will this fact account for the habit? Do the cattle lick bones in search of lime?

Can any of your readers account for this strange taste in cattle?

I may mention that horses and other herbivorous animals in Natal do not exhibit the same taste. H. C. DONOVAN

Delagoa Bay, July 20

THE AUGUST PERSEIDS

THIS remarkable meteor shower recurring annually on August 10 is looked for every year with increasing diligence. To Quetelet belongs the credit of having first (in 1835) ascertained the epoch of its maximum display, though the month of August had long been known as one in which there was an abundance of falling stars. As early as 1762 Muschenbroek, in his work on "Natural Philosophy," stated that, according to his own observations, there were more shooting stars in August than at any other period of the year, and his remark is perfectly true applied to the first half of that month, though it is questionable whether the last half of August will bear comparison with that of July, when meteors fall very plentifully, and constitute a periodical display of special note on the 27th–31st. Since Quetelet determined the date of the Perseids, they have been expected every year with great interest, and from the time that Heis first began systematically to register the paths of meteors (nearly half a century ago) to the present day, observers have continued to record the successive apparitions of this prominent star-shower, so that multitudes of its meteors are now accumulated in the catalogues of British and foreign astronomers.

These Perseids appear to have belonged to our system at a very remote epoch, and to have been observed in considerable intensity as far back as the ninth century of our era. They form a continuous ring or zone of particles. The stream may vary in richness, that is to say, the particles may be very unequally distributed along the orbit, but it seems unbroken and manifests itself every year with more or less intensity from its accustomed point, yielding many bright meteors of great swiftness, and almost invariably accompanied by phosphorescent streaks. It was from careful observations of the Perseids that Schiaparelli, in 1866, was led to his theory of the connection or identity of comets and meteors, and the first orbital coincidence found was that of the Perseids with Comet III. 1862, which seems to have been merely the nucleus or condensation of the particles forming this remarkable meteor system.

The annual returns of this shower as observed and described by various observers, when compared together, show that in certain years the display is exceptionally brilliant; in others it is far less imposing. Eduard Heis, at Münster, counted 155 meteors per hour on August 10, 1863, yet on the same night in 1867 the figures had fallen to 24 per hour. He gives the following as the horary numbers derived from observations between 10h. and 12h. at several stations in Germany on August 10 in different years:—

Year.	Station.	Hourly number.	Year.	Station.	Hourly number.
1841	Aachen	47	1863	Münster	155
1842	Aachen	60	1863	Gaesdonck	215
1847	Aachen	55	1863	Peckeloh	109
1850	Aachen	37	1864	Gaesdonck	106
1852	Münster	89	1864	Rom	63
1853	Münster	56	1867	Münster	24
1858	Münster	88	1867	Peckeloh	39
1861	Münster	78	1867	Papenburg	44
1861	Gaesdonck	102	1871	Peckeloh	93
1861	Peckeloh	102	1872	Rom	64
1861	Rom	89	1874	Rom	110

Maximum in 1863, minimum in 1867 and 1850. There were also many Perseids in 1839, when Heis counted 160 per hour. The displays of 1863 and 1871 were of considerable intensity. On August 10, 1863, 9h. to 13¼h., Heis, assisted by several other observers at Münster, registered the paths of 602 shooting stars, and at Gaesdonck on the same night, 563 were recorded between 9h. 17m. and 12h. 9m. It may be mentioned as a curious anomaly, showing how much "personal equation" may have to do with the estimation of meteor magnitudes, that at the two stations referred to, the meteors were classified as follows:—

	1st mag.	2nd mag.	3–6 mag.	Number with streaks.	Total meteors.
Münster	224	226	151	300	601
Gaesdonck	37	84	442	158	563

The Münster observers evidently overrated the magnitudes to an enormous degree.

The display of 1871, though less decided than in 1863, was still a very rich return of these meteors. On August 10 in that year, Signor Bassani, at Cosenza, in Italy, assisted by Signor Scrivani, counted 674 meteors from 9h. to 16h., and at Boston, Mass., Messrs. Sawyer and Stephens, watching the sky from 10h. to 15h. on the same night, recorded 567 meteors. Since that year the displays have not been of special brilliancy, though on August 10, 1874, 281 meteors were counted at Bristol by the writer in a watch of four hours, from 10.45, to 14.45, and on August 10, 1877, 354 meteors were seen in the five hours, from 9.30 to 14.30, giving an hourly number (for one observer) in both years of about seventy.

Dr. Phipson suggested[1] it was to be inferred from the observations that a maximum occurred at intervals of eight years. There had been considerable showers in 1839, 1847, and 1863, and he pointed out that a similar manifestation was due in 1871. In that year we had, as already described, an unusually numerous return of these meteors, and if the suspected periodicity held good, there would be another rich shower in 1879. Perhaps on that account the Perseids of the present year were anticipated with a little more than ordinary interest, but the night of August 10 was generally overcast in England (though at several stations a few meteors were discerned through breaks in the clouds), and thus the chief display has escaped us, though we may yet receive favourable reports

[1] See his "Meteors, Aerolites, and Falling Stars," p. 159.

from foreign observatories. The nights of August 9 and 11 were partly clear, and a few observations were obtained. Mr. H. Corder, in Essex, saw 166 meteors on the 11th, between 9.30 and 15.30, and found the radiant point very distinct at $45° + 57°$. On August 4 a few meteors were seen from one of the earlier radiants at $33° + 51°$, and on the 6th from another at $36° + 58°$. On the 9th he watched from 9h. 30m. until 13h. seeing only 33 meteors (23 Perseids), but the moon was up and there were a few clouds. On the 10th it was cloudy except between 12-12.30, but a few meteors were seen later, in all 21, 18 being Perseids. The horary number cannot have been much over 30. On the 12th in 2h. he recorded 22 meteors (14 Perseids). Two fine meteors were seen on the 10th, the first, at 12.25, gave a vivid flash low down in Cetus, but only the streak was well seen. It was one of those instantaneous meteors often seen amongst the Perseids. Another was noted earlier (at 10.30) in Ursa = Sirius, and leaving a fine streak.

At Welling, in Kent, 50 meteors were counted by two observers from 10.15 to 11.15.

At Debenham, Suffolk, on August 10, 12 meteors were seen between 10.30 and 11.5, but the sky was much clouded. On the 11th, 10 to 11.30, 95 were recorded by one observer. These figures indicate a somewhat numerous return of the Perseids on August 11. The radiant point was deduced as at $46\frac{1}{4} + 57\frac{1}{2}$.

At Blackheath, S.E., Major Tupman found the normal radiant at $45° + 56°$ on August 11, and describes the Perseids as a poor display between 10.15 and 12.

At Bristol, on August 9, 33 meteors were seen by the writer between 9.30 and 12, but there was much interference from clouds. On August 11 20 meteors were noted in the half-hour preceding 10.10, and 15 of these were Perseids. Radiant point fairly well defined at $46° + 58°$.

It will be seen that the four determinations of the radiant here given almost coincide at $45\frac{1}{2}° + 57°$, and prove the meteors to have exhibited an exact and distinctly marked centre of divergence this year. Mr. Greg's average position for the Perseids, derived from a large number of former observations, is at $44° + 56°$, and the writer found, in 1874, 1876, and 1877, a sharply defined radiant at $43° + 58°$, but has more recently detected the existence of two other simultaneous showers from χ and γ Persei.

Signor Denza reports (*Gazetta Piemontese*, August 27 and 28) that a total of 1,155 shooting stars were observed on the nights of August 9-12 at seven Italian stations, chiefly at Volpeglino, by Signor Maggi and his assistants. The greatest number were recorded on August 11. The Italian observers also succeeded in registering 295 meteors on twelve nights in July.

The apparent diffusion of the Perseid radiant point, often noticed by observers, is explained by the activity of many concomitant showers. Observations of the paths much foreshortened and close to the centres upon which they converge are the best to rely upon in getting accurate radiants. The vast number of simultaneous or contemporary systems in operation is shown by a discussion of a portion of the mass of observations which have been collected on the night of August 10. There are certainly more than 60 distinct meteor streams visible on that single night alone, and evidence of many others whose feebleness allows them to elude discovery. The extreme tenuity of some showers is such that no indication of their existence may be detected in a persistent watch of several hours' duration.

The true Perseids are characterised by the swiftness of their flights (the theoretical parabolic velocity being 38 miles per second) and by the bright and often enduring streaks left in their courses. They are sometimes very brilliant, ending in green flashes of remarkable lustre, and the luminous wands they leave behind guide the eye unerringly back to the point of space whence they are directed. They may be most favourably seen in the morning hours, when the radiant has attained considerable altitude; and the observer should take up a position commanding an uninterrupted view of the north-eastern constellations.

The limits of duration of this shower have not been definitely ascertained, but very few Perseids are visible before August 5 or after August 15. It is certain that they open as early as August 5, because Heis, in 1864, saw a stationary meteor on that date, as brilliant as Venus, exactly in the radiant point at $44° + 57°$. None of the real Perseids are visible as late as August 21, 22, or 23, for of many shooting-stars seen on those dates this year, not one could be certainly attributed to that stream. It was formerly considered probable that the shower began at the end of July, but from the paths of hundreds of meteors recorded by the writer at Bristol during this epoch, there is little if any indication of the true Perseid radiant point. There is, however, a very rich display of swift streak-leaving meteors from a point below χ Persei, or more exactly at $32° + 53°$, with which the old Perseids have been confounded, and given that shower an apparent duration far beyond the actual limits.

In addition to August 10 there are other nights in that month when shooting-stars should be looked for and their horary numbers and radiants ascertained. Large meteors have been recorded in exceptional frequency on the 19th-20th and 22nd, and a series of three fine nights, occurring consecutively this year, on August 21, 22, and 23, enabled the writer to obtain observations as follows:—

Date, 1879.	Time. h. m. h. m.	Duration, hours.	Meteors seen.	Sky.
Aug. 21 ...	9 30–13 30 ...	4 ...	68	Clear; stars very brilliant.
,, 22 ...	9 0–15 15 ...	$6\frac{1}{4}$ ...	70 ...	Partly cloudy.
,, 23 ...	9 15–15 0 ...	$5\frac{3}{4}$ ...	73	Clear; clouds at 15h.
Aug. 21-23...	9 0–15 15 ...	16 ...	211	

Not many large meteors were observed, but three of them were as bright as Jupiter. On the night of August 22 there was slight interruption from clouds, and the watch sustained for $6\frac{1}{4}$ hours under such conditions was not equivalent to more than about 5 hours of clear sky. Of the 211 meteors seen, no less than 52 belonged to a splendidly well defined and rich shower of Draconids from a point at $291° + 60°$, which thus apparently constitutes a special display at this epoch, and one of far more than ordinary importance. On August 21, 21 of its meteors were seen; on August 22, 11; and on August 23, 20. They are slow-moving, bright meteors, sometimes trained, and almost invariably with short paths. The maximum occurred on August 21, when in $\frac{3}{4}$ hour before 10.15, 9 of the meteors were traced, though, singularly enough, during the next hour the radiant gave no visible sign. It is not a new system, for the same shower has been seen by many observers, and is No. 78 of Mr. Greg's Catalogue of radiant points (1876), in which the centre is given at $282 + 60$ (12 obs.), and the duration from June 28 to August 25 (?). Major Tupman detected it in 1871, on August 20-25, at $280° + 58°$, and Corder, in 1877, saw 11 meteors from $307° + 65°$, on August 17, which may have been another manifestation of the same stream. In future years these Draconids should be anticipated as a rich and interesting periodical display. Though none of the true Perseids were visible on August 21-23 this year, there was a moderately strong shower near α Persei, at $46° + 47°$, giving bright, swift meteors, with streaks, and other radiant points were indicated in Perseus at $61° + 50°$ and $62° + 35°$, but no shower derived from the 211 meteors seen on August 21-23, would bear any comparison to that of the Draconids referred to.

The night of August 24 was overcast, but on August 25, before midnight, 14 meteors were seen through openings in the storm-clouds. There were four Draconids, two of

which were brilliant. One was observed in the twilight and moonlight at 8.30 falling vertically in Delphinus, and the other, at 9.57, was as bright as Venus, and gave a succession of three outbursts. Path from 79° + 76° to 89° + 67°. There was a vivid flash at the end point which many persons who did not see the meteor itself mistook for lightning. W. F. DENNING

OUR ASTRONOMICAL COLUMN

BIELA'S COMET.—In the actual uncertainty with regard to the present condition of Biela's comet, the importance of an exhaustive survey of the eastern sky during the dark mornings, *i.e.*, the moonless mornings, of September and October, can hardly be exaggerated. The comet may possibly have been so disintegrated by this time that nothing further will be seen of it as such, but there must remain very great doubt as to such being the case. According to M. Otto Struve's observations of the two heads in 1852, their diameters were still considerable, that of A being upwards of 20,000 miles, and of B 37,000 miles, and the brightness of the latter was equal to that of a star of Argelander's ninth magnitude.

With respect to the most promising plan of search, not much, perhaps, can be said, but if a number of observers are available, as it is to be hoped there may be, sweeps in zones of declination between pretty wide limits of right ascension, appear likely to insure some justifiable conclusion as to the comet's present state or position. Prof. Winnecke, we believe, is in possession of a 6-inch refractor, mounted as an "Airy's orbit-sweeper," and if the comet, or what remains of it, be still moving in the old orbit, this instrument, in such hands, will be of the utmost value in the examination of the proper sweeping-lines for the particular dates. But if the orbit has been sensibly changed by further perturbation, the effect of which is wholly unknown to us, the necessary survey of the heavens will be, of course, only partially effected by this means, so that our only resource appears to be, as we have suggested, in a well-organised scrutiny of that portion of the sky wherein it is possible the comet might be situated, and there is yet time to provide for this, if arrangements have not been already made at those observatories which are occupied with cometary observations. To indicate the portion of the heavens in question, we subjoin the comet's places for the dates of new moon in September and October, according to different assumptions as to its distance from the perihelion, with similar places for five days subsequently:—

Days from perihelion.	September 15·5 R.A.	Decl.	Dist.	September 20·5 R.A.	Decl.	Dist.

THE CLUSTER ABOUT κ CRUCIS.—In a communication to the Paris Academy of Sciences on August 25, M. Cruls, Director of the Observatory at Rio Janeiro, states that on comparing the present appearance of the stellar cluster about κ Crucis, with the map and observations made by Sir John Herschel, he finds notable changes—confirmed by detailed micrometrical measures which he intends to publish. Three double stars are found to be certainly in orbital motion, and there is a rectilinear displacement of the star near the red one. M. Cruls also mentions that he has registered a star 6·5m., which he believes has not been previously remarked, and which he suggests may be variable; it follows B.A.C. 4308 = Lacaille 5293 by 1m. 4·26s., and is south of it, 4′ 14″·6; according to Mr. Stone's position of this star for 1875·0, the place of M. Cruls' object for the same year is in R.A. 12h. 44m. 58·52s., N.P.D. 149° 43′ 11″·0. We notice that the differences given by him are almost precisely the same as the differences between Lacaille 5288 and 5293, though that in declination appears to be in the wrong direction; thus, Mr. Stone's catalogue of 1875 makes the position of 5293 with reference to 5288, in R.A. + 1m. 4·72s., in Decl. + 4′ 10″·4. Is it possible that there can be any confusion here? Mr. Stone has not observed a star in M. Cruls' place.

This cluster is *h.* 3435, and Sir John Herschel's micrometrical details relative to 110 of its components, will be found at p. 17 of his Cape volume; it is remarkable for the various colours of the stars, an attempt to illustrate which is made in the last edition of Chambers's "Descriptive Astronomy."

GEOGRAPHICAL NOTES

THE news of the arrival of Prof. Nordenskjöld at Yokohama on the evening of September 2, will have been received with satisfaction by the whole civilised world. The long-looked for solution of the problem of the North-East Passage has thus been practically accomplished. After being imprisoned in the ice near the Tshuctshe settlement for 264 days, viz., from September 28, 1878, until July 18 last, the *Vega* was at last released, and passing the East Cape, Behring's Strait, on July 20, entered St. Lawrence Bay, which may be said to form part of the Pacific Ocean. Crossing to Port Clarence on the American coast, a short stay was made there, and then the Professor re-crossed to Komian, while all the time dredging operations were carefully made, the formation of the sea-bottom at this spot being particularly interesting on account of the meeting of currents from the Arctic and Pacific oceans. No doubt the *Vega* will bring home a rich collection of specimens. The voyage was then continued, and after touching at St. Lawrence Island, Prof. Nordenskjöld visited Behring's Island, off the east coast of Kamtchatka, where he received the first news from Europe through the resident agent of the Alaska Trading Company. It was here that the professor discovered the fossil remains of the gigantic marine animal *Rhytina stelleri*.[1] On August 19 he left the island and continued his journey towards Japan. On the 31st the ship encountered a severe gale, during which the maintop was struck by lightning, which also slightly injured several of the crew. Without further accident the *Vega* anchored at Yokohama at 10.30 P.M. on the 2nd inst., where she will remain for a fortnight. No deaths took place on board since the vessel left Sweden last summer, and thus the high-minded liberality of Herr Dickson, of Gothenburg, who supplied the means for the spirited enterprise of Prof. Nordenskjöld, is by the complete success of the latter deservedly rewarded.

In the August number of Petermann's *Mittheilungen* the narrative of journeys and voyages to Siberia is continued, with a map showing the most recent voyages through the Kara Sea. A special map has also been issued in which a portion of the course of Nordenskjöld in the *Vega* is laid down. The new coast-line of North-East Siberia is also laid down from the data supplied

[1] This animal was a species of Sirenia, and was exterminated by man within a comparatively recent period. It was discovered about the middle of last century upon the island in question, which has its name from the celebrated traveller who was wrecked there in November, 1741, and who found the place inhabited by large numbers of these enormous animals. They were first described by Herr Steller, who was one of Behring's party. The discovery, however, seems to have been fatal to Rhytina, none having been seen later than the year 1768.

by the Italian naval officer, Lieut. Bove. *Apropos* of recent troubles between Chili and Bolivia is an article, with map, on the desert of Atacama. Among the information in the *Monatsbericht* are a number of important data as to the heights of various places in Japan.

AT the last annual meeting of the Swiss Alpine Club the following resolutions were adopted:—(1) The club determines for six years the field of its excursions as follows:—The high Alps between the cantons of Berne and Valais to be explored from west to east in three parts: the Lenk with its neighbourhood, the Blumlis-alp, and the glacier of Aletsch and the Jungfrau as far as Grindelwald; (2) A series of lectures will be opened for the guides; (3) The central committee will publish all interesting documents collected until now as to the motion of glaciers, with bibliographical notes on former publications on this subject.

THE new number of the Geographical Society's monthly periodical contains Mr. Keith Johnston's "Notes of a Trip from Zanzibar to Usambara, in February and March, 1879," illustrated by an excellent little map, which has been reduced from the original drawing sent home by him. These and the other reports and maps connected with his preliminary work, and published in a previous number, were, as the editor very truly remarks, "a sure promise of great things to come when he should have traversed the unknown regions of the interior," and show very clearly how great a loss geography has sustained by Mr. Johnston's premature death. Notes on the geology of Usambara, collected during the same journey, are by Mr. J. Thomson, the geologist and naturalist of the East African expedition, who has now taken Mr. Johnston's place. The "Lecture on the Origin of the Flora of the European Alps," by Mr. John Ball, F.R.S., occupies a considerable portion of the present number. The geographical notes do not this month contain anything very striking, but some of them are good, especially those relating to Col. Grodekof's and M. Oshanin's expeditions, and to the exploration of the Sanpo River and Count Szechenyi's further attempt to reach Lob-Nor from China. We would also call particular attention to the obituary notice of Mr. Keith Johnston. The rest of the number is chiefly occupied with the presidential address in the Geographical Section of the British Association.

A PROPOSAL similar to the often-ventilated plans of a sea in the great Sahara has been recently made by the Governor of the State of Arizona, in North America. It is suggested that a short canal should be constructed which would admit the waters of the Pacific to a large and low-lying area of land situated between Arizona and Southern California. The district is quite a desert at present, and is believed to be the bed of an ancient lake. It measures some 200 miles in length and 50 miles in breadth; its level is estimated to be about 300 feet below that of the Pacific. Its western boundary is at only 45 miles distance from the Gulf of California, and as on this part, where the canal would have to be built, there is already a lake of 20 miles length, the length of the actual canal would be reduced to 25 miles. The cost of the undertaking would amount to about 200,000*l*., and the work could be completed in six months. The importance of an undertaking of this kind need not be pointed out.

WE learn by telegram from New York that Commander Lull, U.S.N., has read a paper before the American Science Association, on his recent explorations in connection with the proposed ship-canal through the Panama Isthmus. He considers that the only practicable routes are those *viâ* Nicaragua and Panama, and that locks will be indispensable. Commander Lull gives a decided preference to the Nicaragua route.

THE last number of the *Isvestia* of the Russian Geographical Society contains much interesting information as to the meetings of the Society and of its sections. Unhappily, all the proceedings are very old, as we do not find anything more recent than from February 6 to May 30 of last year. It is a pity that the Society does not publish its interesting proceedings immediately after the meetings.

M. HOEVERT has undertaken a valuable work, the compilation of a complete bibliography of all works relative to the geography of Russia published till now. He has already finished the revision of the libraries of the Geographical Society of the Academy of Sciences (which receives *all* Russian works published), and of the General Staff.

WITH a view to turning the island to profitable account, a Saghalien Fishing Association has been established under licence from the authorities at St. Petersburg, and vessels for the purpose are being built or chartered in Japan. The business is expected to prove a very lucrative one.

THE caravan of Capt. S. Martini, whilst on its way to convey supplies to the Italian African expedition, has been attacked by the Somalis tribe and robbed of all its merchandise at a distance of some six day's march from Zeila.

NOTES

THE eighth general meeting of the German Astronomical Society took place at the lecture hall of the Royal Academy of Sciences at Berlin on the 5th inst., under the presidency of Prof. Krüger, Director of the Gotha Observatory. Numerous guests from England, France, Belgium, Holland, Russia, Sweden, Denmark, and Austria were present. The Minister for Public Instruction, Herr von Puttkammer, welcomed the assembly in the name of the German Government. We shall refer to the meeting in a future number.

A SMART shock of earthquake was felt in the neighbourhood of Szegedin (Hungary) on September 3.

AN announcement made by the Society of Arts states that the Society offers the Fothergill gold medal for the best means of protecting ships from loss by fire and by sinking, and a silver medal for the protection of ships from either calamity.

A PAMPHLET containing a collection of necrological notices of the late M. Victor Masson, formerly principal of the eminent Paris publishing firm, has recently been published in Paris. The deceased died at his country house of Chassagne (Côte d'Or) on May 3 last, at the age of seventy-two years. His name was well-known in all scientific circles, as he held the highest place among scientific publishers of the French capital. Personally he was greatly esteemed by all who knew him, his relations with men of science were ever of the most liberal, friendly, and upright character, and the care and elegance with which he brought out the scientific works entrusted to him always deserved special praise.

ON the 25th inst. the Pompeii celebration, to which we referred some time ago, will take place. The director of archæological excavations in Italy, Prof. Michele Ruggiero, will deliver a historical address to the assembled guests in the basilica of the ruined city. Hereupon he will lead them through the entire area hitherto laid bare, and afterwards some excavations will be made in presence of the guests.

THE Clothworkers' Company have voted 3,500*l*., beyond the 10,000*l*. previously voted, to cover the complete cost of that portion of the buildings of the Yorkshire College of Science, Leeds, which will be required for the teaching of the sciences applied to the textile industries and dyeing. They have further agreed to maintain the buildings and the operations in full effect for a period of five years from January 1 next, at a cost of 1,200*l*. per annum.

PROF. A. H. CHURCH commences a course of ten lectures on the Chemistry of Food next Monday, the 15th inst., at five o'clock, at the National Training School for Cookery, Exhibition Road, South Kensington. Mr. Church has been appointed Professor of Chemistry at the Bedford College (for ladies), York Place, Portman Square.

THE sixth Congress of Russian Naturalists promises to be very interesting, not only as to the scientific communications expected, but also as to its practical results. It is proposed to form a permanent Commission of representatives of all Russian scientific societies for the exploration of little-known parts of Russia as to their natural history and geology, with the special aim of the applications of science to agriculture and mining industry. Another Commission will be nominated for the diffusion of science among the masses of the people by means of a series of systematical lectures. A group of Russian explorers of the North proposes to form at the Congress of Naturalists a special section for all questions connected with the exploration of the North of Russia and Siberia.

THE *Courier de Tlemcen* (near Algiers) describes an interesting if somewhat fabulous discovery. It states that some miners occupied in blasting rocks in the vicinity of the picturesque cascades, discovered the entrance to a cave, the floor of which was covered with water. They ventured upon the subterranean river on a raft, and followed it for some 60 metres' distance, when it disappeared in a vast lake. Here the vault of the cave was very high and covered with stalactites. In many parts the miners had to steer their raft between colossal stalactites which reached down to the surface of the water; eventually they reached the end of the lake, where they noticed a canal extending towards the south, and into which the waters of the lake flowed. The workmen estimate the length of the lake to be 3 kilometres, and the breadth about 2 kilometres. They brought out a quantity of fish, which, they say, surrounded the raft, and which were found to be blind.

THE optical structure of ice forms the subject of a recent paper by Herr Klocke, in the *Neues Jahrbuch für Mineralogie* (1879, p. 272). He confirms M. Bertin's observation, that in formation of ice the optic axis of the crystal is placed at right angles to the surface whence the cooling proceeds; and this was the case with water at rest in a freezing mixture. Only the ice-flowers which first cover the sides of the vessel have their principal axis parallel to these. M. Bertin affirmed that the first thin ice-layer forming on water which freezes in an open vessel in cold air has a confused crystallisation, and only after thickening takes a determinate orientation. Herr Klocke differs from him here. He shows that the first needles shooting over the surface are formed parallel to the principal axis, and that then ice-plates are added to their sides, whose optic axis is at right angles to the surface of the water. In the enlargement of these lateral plates to the table of ice extending over the whole water surface, this orientation is preserved from the commencement. Tables of ice quickly formed under disturbing influences or in great cold, as also various plates of sea-ice, showed, on the other hand, aggregate polarisation. Various other observations are described.

WE hear that the preliminary operations for opening the coal-mines in the Kaiping department of the Chinese province of Chihli, to which we have before referred, are proceeding satisfactorily. From borings made last winter it would appear that six seams of good coal can be reached, and the construction of two shafts has been commenced. Good clay has been found close at hand, from which bricks will be made for lining the lower parts of the shafts, the upper portions being faced with stone already prepared for the purpose. Machinery and some miners were shortly expected to arrive from Europe, and the work would then be rapidly pressed forward.

THE temperature of the polar extremities of carbons giving the electric light has been recently investigated by M. Rossetti (*Journ. de Phys.*, August), using the same method and instruments as he used in measuring the temperature of the sun. (The face of a thermo-electric pile is placed at suitable distance to receive rays from a radiating surface of determinate size, and the thermal effect is measured by a very sensitive Wiedemann reflecting galvanometer; the temperature is deduced by means of a formula previously established.) We give, briefly, the author's conclusions:—(1) The positive carbon pole, at the moment of production of the light, has always a higher temperature than the negative. (2) These temperatures vary according to variation of the current's intensity. (3) They are higher the smaller the radiating surface, provided, of course, it comprises the extremity of the point. (4) For the negative pole the minimum temperature was 1,910° C., the radiating surface being large and, in part, of small brilliancy; the maximum 2,532° C., the radiating surface being half the preceding. (5) For the positive pole, the minimum temperature was 2,312°, the carbon being very large and the radiating surface very extensive; the maximum 3,200° when the carbon was thin and the radiating surface nearly a quarter of that corresponding to the minimum temperature. (6) We may consider the temperature of the extreme negative polar point as equal to 2,500° at least; that of the positive polar extremity is not less than 3,200°.

ON Saturday last a system of telephonic communication highly promising for the convenience of business men and others was successfully inaugurated in London. The telephone used is that of Edison (the loud speaking telephone), with the nature of which our readers are acquainted. A central station called the Telephone Exchange, in Lombard Street, is put in connection at present with ten private offices furnished with telephones in various parts of the city. The switch-board at the central office might be connected with twenty-four different stations, this being the most that can be attended to by one person. Any number of switch-boards, however, might be added in the same room, and any station on one board connected with any one on another board. An attendant, who may be a boy, sits in front of the board. Supposing No. 2 wishes to speak with No. 6, the person at No. 2 calls the attention of the central attendant by means of an electric bell, while a falling shutter on the switch-board shows the number of the applicant. The attendant responds, and No. 2 then says, "Connect me with No. 6." The shifting of a pin effects this, and Nos. 2 and 6 are left to communicate with each other. When the conversation is closed, No. 2 signals by the bell that he has finished, and the attendant, removing the pin, separates the two stations. And so with any other numbers. Of course only one station can be connected with another at the same time, but the process of coupling and uncoupling is effected very quickly. Edison's instrument, though known as the loud-speaking telephone, is also suited for conversation almost in whispers, and this was tested on Saturday with very satisfactory results. The telephone is said to have been worked in America without difficulty between stations 100 miles apart. It is considered that up to about five miles distance there is no loss of power; and in practice of the above system even five miles would probably be found an exceptional distance. The utility of the system seems fully demonstrated, and we may look for an extensive application of it in our large towns.

THE common form of speaking telephone relies for its action on currents of electricity developed in helices by the varying strength of magnetic induction when an armature moves in the magnetic field. A second genus of telephone is that which Edison has developed out of his motograph, and which depends solely on the varying friction between two surfaces, one of which is an electrolyte, when a varying current is passed between them.

Prof. Dolbear has recently (*Journ. of Frankl. Inst.*) described a third genus of telephone quite unlike the other two. A short, straight bar electro-magnet is furnished with a crank, so that it may be rotated within its coil. Lying on the poles are the ends of a bent armature (of horse-shoe form), the back of which is fastened to a plate of mica, or paper, or thin iron, mounted as in ordinary receivers, so that any motion of the armature poles will be imparted to the plate. When a current traverses the bobbin, the straight bar becomes a magnet, with strength proportionate to the strength of the current, and the armature adheres to the poles of it with a certain strength of adhesion. Now let the crank be turned slowly, and the adhesion of the armature will result in stretching the plate, and the cessation of the current will let the plate regain its former position through its elasticity. A varying current will result in varying adhesions and consequent vibrations of the plate, and talking may be plainly heard with an instrument constructed thus. Prof. Dolbear calls it the *Rataphone*. Of course there are various ways in which the principle may be utilised.

In the last number of the *Astronomische Nachrichten* Dr. Hermann J. Klein, of Cologne, publishes some further remarks regarding the new formations near the lunar crater Hyginus, which were first noticed by him, and about which there has been so much discussion in astronomical circles of late. Dr. Klein, after giving some valuable selenographical details (for which we must refer our readers to the serial mentioned), observes that for the present it must remain undecided whether the new formations near Hyginus are due to volcanic action. As far as his knowledge extends, only one observation of lunar changes may be ascribed to phenomena of a volcanic nature. This observation was made by Schröter and Olbers on July 2, 1797, and referred to a mountain, V, in the Mare Vaporum. The mountain was found to be 3,450 feet in height, and has never again been seen; it was probably only a mass of vapour. Almost at the very spot where this mysterious object was observed a crater is now visible. Dr. Klein is of opinion that at the surface of the moon masses of vapour are formed now and then and are of considerable duration, and he lays particular stress on the fact that for certain processes taking place upon our satellite all analogy with terrestrial phenomena is completely wanting. As an instance he points to the occasional occurrences at the double crater Messier. Those who are acquainted with the entire materials collected by observations of this formation, from Gruithuisen down to Schmidt, and who have themselves for some time observed the crater and its appendages, will own that here they stand before an unsolved enigma, and that, for the present, at least, it is the wisest course to abstain from any attempt at explaining the wonderful phenomena which are taking place in those regions.

The Austrian geologists are very busy at present with the excavations which are being made in the Moravian caves of Stamberg and Brünn. A few miles from the latter town the celebrated Vypustek cave is situated. This is now being investigated by order of the Imperial Academy of Sciences of Vienna, and has been repeatedly visited by Prof. von Hochstetter. The Imperial Museum at Vienna has quite recently received a collection of bones of the cave-bear, of the cave-hyæna, and of other prehistoric inhabitants of the Vypustek cave.

In a recent number we referred to the tides observed in the subterranean waters of a coal mine at Dux, Bohemia. A similar phenomenon is reported from America, where it was observed in an artesian well some months ago. A Vienna geologist therefore recommends that observations should be made at the artesian wells in Europe, to ascertain whether similar phenomena would show themselves.

In an article in the August number of the *Entomologist's Monthly Magazine*, on the recent abundance of *Vanessa cardui* over a great part of Europe, Mr. McLachlan suggests that possibly "the insect may be able to rest quiescent in the perfect state over a series of years, until the accumulated numbers simultaneously wake up."

The Russian Commercial and Technical Societies propose to send to the Berlin International Fishing Exhibition several collections of living fishes and detailed descriptions of the fishing in Russia.

In the last (August) number of the *Annali di Chimica applicata alla Medicina* of Dr. G. Polli of Milan, an interesting note by Dr. Finardi Sante of Salara (Rovigo), reports the discovery of a new method of conserving chloride of lime unchanged, *i.e.*, free from carbonate or moisture. It consists in placing into the jars containing this substance a small vessel containing a mixture of salicylic acid and salicylate of potash, then closing the jars with a non-porous stopper and preserving them in the dark.

We have received the *Anuario del Observatorio de Madrid* for 1876 and 1877; it contains much useful astronomical and statistical information. We have also received the meteorological publications of the same observatory for 1875–8; these we hope to notice at length.

During a thunderstorm at St. Cergues, in the Jura, the rare phenomenon known as St. Elmo's fire was observed. A pine forest in that neighbourhood is reported to have appeared as if on fire, presenting a magnificent aspect.

A step in the right direction has been taken by the citizens of Colorado in the formation of a Historical and Natural History Society at Denver. The leading citizens of the State have become members of the new society, the main object of which is the preservation of records, documents, relics, &c., referring to the State of Colorado. The accumulation of works on natural history and of specimens illustrating the natural wealth of the State is another object the Society has in view.

In a note to the Berlin Physiological Society, Herr Fritsch, after remarking on the difficulty of rendering bacteria in infected tissues visible, recommends Abbé's illuminating arrangement for the purpose. This consists of a hemispherical lens-system, the plane surface of which is placed close under the object. To the middle point of the system is directed a considerable quantity of daylight by means of a plane mirror, and the intensity is so regulated that, with different combinations, differently incident cones of rays are obtained.

The additions to the Zoological Society's Gardens during the past week include a Tiger (*Felis tigris*), two Indian Leopards (*Felis pardus*), from India, presented by His Excellency the Right Hon. Lord Lytton, G.C.B., G.M.S.I.; a Macaque Monkey (*Macacus cynomolgus*), a Bonnet Monkey (*Macacus radiatus*) from India, presented by Mr. B. Raver; two great Bustards (*Otis tarda*) from Andalusia, presented by Mr. Forster; two All Green Parrakeets (*Brotogerys tiriacula*) from Brazil, presented by Dr. A. Stradling; two Common Chameleons (*Chamæleon vulgaris*) from Cyprus, presented by Mr. Alfred Ely; a European Bearded Vulture (*Gypaëtus barbatus*) from Spain, deposited; a Sœmmerring's Gazelle (*Gazella Sœmmerringii*) from Abyssinia, a Rock Cavy (*Ceredon rupestris*), a Crab-eating Opossum (*Didelphys cancrivorus*), an Ashy-headed Goose (*Bernicla poliocephala*), an Upland Goose (*Bernicla magellanica*) from South America, a Superb Tanager (*Calliste fastuosa*), a Black-shouldered Tanager (*Calliste melanonota*), a Palm Tanager (*Tanagra palmarum*), a Thick-billed Violet Tanager (*Euphonia crassirostris*), a Brazilian Blue Grosbeak (*Guiraca cærulea*), two Tuberculated Iguanas (*Iguana tuberculata*), two Horrid Rattlesnakes (*Crotalus horridus*) from Brazil, two Elegant Parrakeets (*Euphema elegans*), from South Australia, two King Crabs (*Limulus polyphemus*) from North America, purchased.

PROF. DODEL-PORT ON THE FERTILISATION OF RED SEAWEEDS BY INFUSORIA

IN a recent number of the excellent periodical *Kosmos*, Dr. Dodel-Port, the eminent Zurich botanist, has published the results of a series of observations made by him regarding the part played by some infusoria in the fertilisation of a certain species of red seaweeds or Florideæ, viz., *Polysiphonia subulata*, T. Ag. The paper is of biological importance, since it forms, as far as our knowledge extends, the first record of a possible participation of animals in the fertilisation of cryptogams, which in itself seems an interesting parallel to the relations existing between insects and phanerogams. We have pleasure, therefore, in presenting our readers with an abstract, the illustrations for which have been placed at our disposal through the kindness of the author and of the publishers of *Kosmos*.

In previous numbers of the same periodical Dr. Hermann Müller had sketched the history of the evolution of the floral world and had shown upon what basis rests the entire relation between flowers and insects. This basis is the passage from a state of things in which the male cells discharged their products in a medium of water to that in which this event took place in the dry atmosphere, which transition period occurred at the upper boundary of the cryptogamic flora of prehistoric times.

In almost all cryptogams, which are not agamic, the contents of the male sexual cells are actively movable; when they leave the male cell they move freely about in the water by means of vividly oscillating cilia. They therefore possess the faculty of moving to the distant female organ, and there to complete fertilisation. In the case of phanerogams, the independent mobility of the pollen-bodies has become an impossibility. To effect the union of pollen-grains with that particular part of the female flower which is destined to receive them, in most plants some external agent must interfere. In many cases, specially in the lower regions of the floral world, the wind, gravitation, or both together, are the agents in question; in the majority of the higher phanerogams, insects, or occasionally other animals, undertake the conveyance of the pollen.

Now there are a great number of cryptogams, in which the contents of the male cells which are emptied into the water do not possess the faculty of independent motion, as they are not endowed with cilia, and are therefore dependent on the action of external forces for their locomotion. To these belongs the great and highly differentiated order of so-called red seaweeds or Florideæ, chiefly marine plants which vary much in form and colour, and which no one who has ever attentively observed on the sea-coast will ever forget. Their antherozoids, which are generally spherical, are discharged into the water as motionless cells, and are yielded up to the play of currents in the same way as in our anemophilous phanerogams, the pollen grains pass as a dust into the air, and are moved to and fro by the winds. There are many analogies between Florideæ and higher phanerogams, regarding their sexual conditions. Thus, amongst the former we find many species which are diœcious, similar to the lowest phanerogams amongst gymnosperms, and to others of higher order. The chances for fertilisation in their case are therefore quite similar to those applying to diœcious phanerogams. Often the male plants grow at a considerable distance from the female plants of the same species. In the spring of 1878 Dr. Dodel-Port, during a series of microscopical examinations of the red seaweeds of the Adriatic, extending over four weeks, found only female and agamic (tetrasporous) specimens of *Polysiphonia subulata*, T. Ag., and looked in vain for male specimens, of which only at the end of his investigations he could obtain a few. Their respective localities of growth were evidently considerably apart, and yet at all times Dr. Dodel-Port found female specimens in all stages of fertilisation. The spermatozoids discharged by the male plants therefore found their way to the distant female plants in spite of their own immobility and general passive behaviour. The sea-water must therefore have frequently been in vivid motion.

These facts being ascertained, the thought easily suggested itself that possibly animals might take part in the fertilisation, particularly as there is never a want of small marine animals roaming about in the Florideæ forests, such as infusoria, crustacea, annelids, starfish, &c. But what particularly attracted Dr. Dodel-Port's attention was the regular occurrence of innumerable bell-shaped animalcules (*Vorticella*) on the shrub-like branches of *Polysiphonia subulata*. In the course of closer investigation of the phenomena of fertilisation in the female organ, during and after the adherence of the antherozoid with the trichogyne, Dr. Dodel-Port eventually arrived at the full conviction that in the case of Polysiphonia the little Vorticellæ facilitate the conveyance of the antherozoids to the trichogyne, and that they act according to a natural law in the same way as do the pollen-collecting bees when by visiting the willow-catkins they assist at their fertilisation. The investigation of the sexual conditions of Florideæ is as yet in its infancy; it is to be hoped that more numerous researches in this direction will shortly be made, and possibly relations may be found to exist between other species of this order and certain animals similar to those discovered by Dr. Dodel-Port in the case of Polysiphonia and Vorticella. The details of the interesting relations in this case are shortly as follows:—

Fig. 1 represents the male reproductive organ (antheridium) of *Polysiphonia subulata* magnified 480 times. These antheridia often appear in large numbers at the upper branch-ends of the male plant, laterally close to the apex which continues its growth, at the spot where, in the vegetative state, young branches would form. In their earliest stage the antheridia consist, like the young branches, of a single row of cells. By repeated longitudinal and lateral divisions a polycellular body is soon formed, which begins with a short stem-cell (*st*), and which, on the side furthest away from the maternal thallus-branch, is protected by a forked hair (*gh*).

The ripe antheridium in external appearance reminds one very strongly of a maize cone; a row of 4–6 cylindrical cells (*a*, *a*) in the axis of the whole organ represent the spine of the cone, while the surface is covered over by numerous antherozoid mother-cells (*sm*, *sm*) representing the grains of maize. Before the antheridium is ripe the latter are polyhedrical, but afterwards they assume a round shape, as the drawing shows. All parts of the male organ are colourless; the antherozoid mother-cells are filled by a finely granular plasma, which is soon differentiated into a round body, which subsequently is discharged from the mother-cell as an antherozoid (*s*, *s*). Thus within a short time the ripe antheridium discharges some 400–800 ball-shaped antherozoids into the surrounding sea-water. The single antherozoid is a little globule of protoplasm, without cell-wall or any locomotive organ. In the centre of this globular primordial cell a strong magnifying power shows a little nodule which strongly refracts light, and round which a few smaller colourless plasma granules are grouped. As it freely floats in the water, the antherozoid is analogous to a pollen-grain of an anemophilous phanerogam.

The female reproductive organ of *Polysiphonia subulata* is a polycellular carpogonium of relatively high differentiation. It originates upon the female plant closely below the apex of the thallus-branches, and generally there are several of them forming successively at varying intervals from the branch-end downwards.

Fig. 2 shows the carpogonium-bearing branch-end of a female specimen of *Polysiphonia subulata*. *cg'* is a very young carpogonium; *cg*, *cg* are two mature ones; *t'* and *t''* are two trichogynes; *Vort.* are two Vorticellæ. The whole is magnified 300 times.

In Fig. 3 a carpogonium (*ca*) is represented magnified still more (480 times). *Vort.* is a Vorticella; *s*, *s* are antherozoids. In the mature state the carpogonium consists of three essential parts, viz.:—

1. The basal portion *f* (Fig. 3).
2. The fertile spore-forming part *cg*.
3. The hair apparatus *t* and *gh*.

The basal portion consists of five tubular cells running parallel to each other, of which in Fig. 3 are seen only two. Then follows the fertile part, *cg*, which is an oval cellular body, consisting of some 20–26 cells. A central cell, copiously filled with granular protoplasm, is surrounded by a number of irregular, peripheric cells, and awaits fertilisation, in order afterwards to transform itself into the spore-forming apparatus, while the remaining 19–25 peripheric cells become the case of the spore fruit through further divisions (see also Fig. 4, *h h*). The uppermost part of the female organ is the hair apparatus, which, in Polysiphonia, consists of the forked hair, *g h*, and the trichogyne, *t* (Fig. 3). The forked hair forms very early upon the young carpogonium, and indeed long before the trichogyne is formed; its position is always upon the true apex of the whole organ, although at times it stands apparently laterally from the apex. The duration of its existence and its presence at the time of fertilisation (it disappears immediately

afterwards) prove it to be an organ of some use in that process. The most essential and important part of the hair apparatus, however, is the trichogyne (*t*, in Figs. 2 and 3), *i.e.*, the receptive organ, which in Florideæ has a similar signification to that of the elongated style in many phanerogams, while the central part, *c g*, of the carpogonium is the analogue of the closed

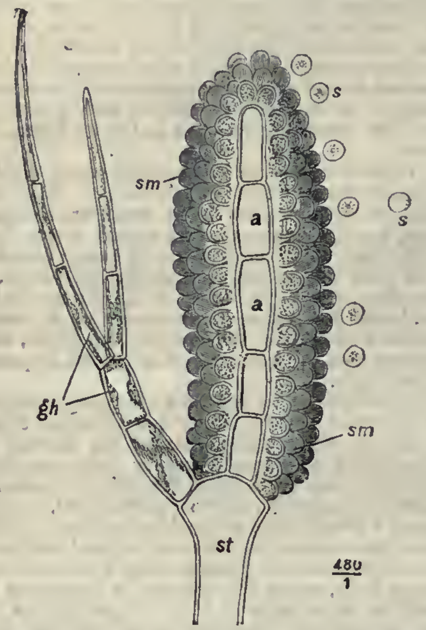

Fig. 1.

ovarium of angiosperms. The trichogyne is a slender, colourless hair, consisting of but a single cell, which rises from the carpogonium laterally from the apex of the latter, and does not quite attain the length of the forked hair, *g h*. It forms just about the time when all other parts of the carpogonium have attained that degree of differentiation which they possess during

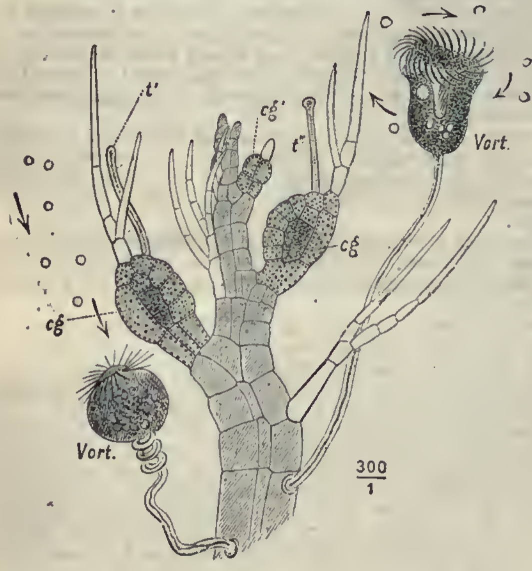

Fig. 2.

fertilisation. In the full-grown state the trichogyne is of the same thickness in its entire length, and rounded off suddenly at the upper end. The narrow canal of the trichogyne contains colourless, finely-granular protoplasm.

Now if antherozoids of *Polysiphonia subulata*, which were freshly discharged by the antheridia and have been accidentally carried near by currents, come into contact with the upper part of the trichogyne, they get firmly attached to the latter. It is particularly the apex of the trichogyne which possesses the faculty of retaining the globular antherozoids. Then the granular protoplasmic contents of the antherozoids pass into the

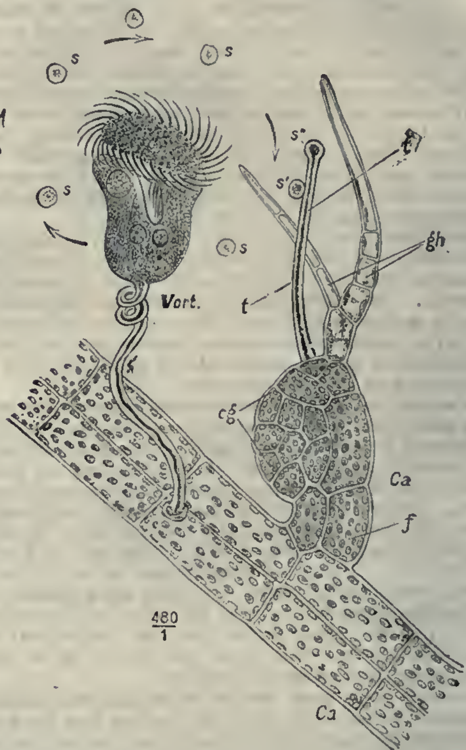

Fig. 3.

interior of the trichogyne (Fig. 3 *s''*). A part of it descends down the trichogynic canal into the carpogonium, giving the fertilising impulse to the central cell of the carpogonium. This process is quite similar to the corresponding one in phanerogams.

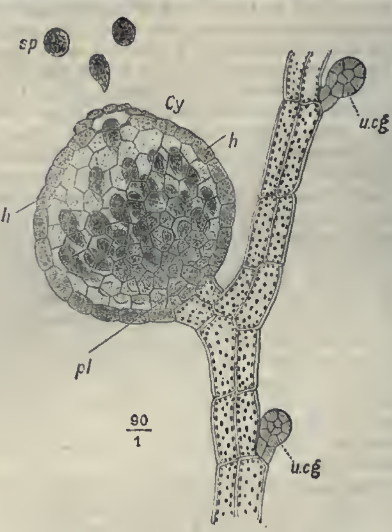

Fig. 4.

As the antherozoids of Florideæ are totally devoid of active locomotive organs, the possibility of fertilisation, *i.e.*, the coming into contact of the antherozoids and the trichogyne, of course rests entirely upon a lucky chance. The antherozoids reach the female organs passively, either by their own weight or through

the currents of the water, caused by waves, wind, or tides, and doubtless in many cases through the incessant movements of some marine animals. The greater the distance between the antheridia and the carpogonia, the smaller are, of course, the chances of fertilisation; the more violently the water is moved about in the vicinity of and between the separated organs, the more probably will the lucky accident of the union of both elements take place.

During a long series of investigations of the reproductive phenomena of Polysiphonia, Dr. Dodel-Port found regularly on the bushy thallus, and particularly upon the uppermost and youngest branches, an enormous number of the well-known stalked animalcules, Vorticellæ, which had settled there, and were, as usual, in incessant motion. Often they appeared in dozens in the field of the microscope, and, with the constant vibration of their cilia, they were very troublesome, at least up to the moment when Dr. Dodel-Port had directly observed their friendly co-operation in the fertilisation he was studying. He was a frequent witness of the process depicted in Fig. 3, where numerous antherozoids were whirled round and round in the whirl caused by a Vorticella, and where frequently antherozoids came into contact with the trichogyne, and remained attached to it (Fig. 3, *s′* and *s″*) for a longer or shorter period. It was entirely due to the motion caused by Vorticellæ that Dr. Dodel-Port was enabled to follow the phenomenon of the attachment of the antherozoids to the trichogyne from beginning to end. The motions of the Vorticellæ are particularly varied through the repeated contractions of their stalks into short spirals, and thus they cause various currents in the water, by all of which the antherozoids are carried along like any other small passive body that may be suspended in the water. (Compare Fig. 2, where one of the Vorticellæ is just contracting its stalk, the arrows in each case indicating the direction of the currents.)

The presence of numerous Vorticellæ thus imparts to the passive antherozoids a kind of motion much resembling that of the sperm-cells of other cryptogams which are endowed with active cilia. From this follows, with mathematical certainty, that the probability of the antherozoid falling on the trichogyne in the presence of Vorticellæ is immensely greater than that which would exist were there no animals present.

At the same time, it is evident that this probability is yet increased in the case of *Polysiphonia subulata* through the presence of the forked hair, *g h*, in the vicinity of the trichogyne, because the whirls caused by the animalcules will often be cleft by the forked hair, and thus secondary whirls will be produced. Often in Polysiphonia, carpogonia were found which were not fertilised. Thus Fig. 4 represents a ripe and spore-ejecting cystocarp, *c y*, and two carpogonia, *u c g*, which remained unfertilised. This was particularly the case on thallus-branches, which were less densely crowded with Vorticellæ—another, although negative, proof of Dr. Dodel-Port's theory. It is not particularly remarkable that Vorticella should inhabit Polysiphonia in large numbers, because these animalcules, as Dr. Dodel-Port observed, feed with predilection on the antherozoids of this plant. Thus we have here a condition of things similar to the relations between certain flowers and pollen-consuming insects. The consumption of antherozoids by the Vorticellæ is, of course, far too insignificant to merit any consideration, particularly if compared to the great advantages regarding fertilisation which the presence of the animalcules brings with it. Moreover, a comparison of the male plant of Polysiphonia with a female specimen shows that here also, as in most phanerogams, thousands more male cells are formed than are necessary for fertilisation.

After fertilisation the carpogonium develops into a cystocarp, *i.e.*, the spore-forming fruit (Fig. 4). Shortly after fertilisation the whole hair apparatus disappears. The wall-cells of the carpogonium now begin to grow quickly and to divide by membranes perpendicular to the surface. They form a cellular case (*h h*, Fig. 4), which has an orifice in the apex, long before the spores are ripe. In the meantime the central cell of the fertilised carpogonium begins to form a number of densely-packed short branches, which, as a series of cells radiating in all directions, fill the basis of the capsule-shaped fruit. The central cell is therefore called the placenta-cell. At the ends of the ramified cell-series which radiate from it, pear-shaped and dark red spores form (carpospores), which, as soon as they have attained a certain size, become detached and pass into the water through the orifice at the apex of the cystocarp. In this state they are perfectly capable of further development and soon begin to germinate.

Dr. Dodel-Port concludes his interesting treatise with the following suggestive sentences:—

"The total absence of active organs of locomotion in the antherozoids of Florideæ points to a common ancestor from which the different branches of the Florideæ have inherited the immobility of the antherozoids. No doubt that during the differentiation of the red seaweeds many forms have died out in consequence of the fertilisation not taking place through the passivity of the male cells, while other forms have retired to localities which through active water-currents favour the process of fertilisation in spite of the immobility of the antherozoids. It is well known that now we find most of the present species of Florideæ on the coasts of warmer seas, which are constantly washed by the waves, while the northern coasts, which are covered by crusts of ice during a great portion of the year, are very poor in red seaweeds. Future researches will have to show how far in many of these aquatic plants the differentiation of the genera took place in the sense of an adaptation to the small marine animals which inhabit them and favour their fertilisation in the way I have pointed out. If many seaweeds in their bushy shrub-like thallus harbour certain infusoria, bryozoa, hydræ, sponges, crustacea, annelids, and small starfishes, and offer to them excellent hiding-places or nourishment, so that these animals inhabit them with special predilection, then it is certainly possible that occasionally a correlation was formed or adaptation took place, which was mutually advantageous and which would find numerous analogies in the domain of the multiple cross relations between the higher flowering plants and insects. In this sense I consider it my duty to submit to the criticism of biologists a point hitherto overlooked in the biology of red seaweeds, and bearing upon the explanation of the morphological differentiation of submerged aquatic plants."

THE BRITISH ASSOCIATION

REPORTS

Report of the Committee appointed for the Purpose of Arranging for the Occupation of a Table at the Zoological Station at Naples, the Committee consisting of Dr. M. Foster, Prof. Rolleston, Mr. Dew-Smith (Secretary), Prof. Huxley, Dr. Carpenter, Dr. Gwyn Jeffreys, Mr. Sclater, Mr. F. M. Balfour, Sir C. Wyville Thomson, and Prof. Ray Lankester.—Since we submitted our last Report to the Association, the Zoological Station at Naples has continued to be successful in providing opportunity and appliances for naturalists studying the various forms of marine animals and plants. From September 1, 1878, to the end of July, 1879, twenty-six naturalists have occupied the tables at the Institution. A list of their names and the time of stay will be found appended. During the same period, packages of specimens have been forwarded to fifty-one different naturalists and institutions. A list of these is also appended.

Recently a new department has been added to the station. Through this naturalists will be enabled to obtain mounted specimens of microscopic animals, viz., sections of embryos of all kinds of fishes, &c., preparations of larvæ or other animals too small for being sent in alcohol or other preservative solutions. Next year a catalogue of these specimens will be published, and the station will be prepared to send the specimens to any naturalist requiring them.

Trials of diving by means of the new Scaphander apparatus have also recently been made with very satisfactory results.

The aquarium of the station is being in part reconstructed, with some important new features, viz., moveable rockwork, for saving and examining the different animals which thrive by themselves on these rocks. This will enable statistical notes to be established on the growth of these animals, and on such changes as may occur by changing their habitat, inasmuch as these rocks may be replaced in the sea at different depths.

The following monographs are in preparation by workers in the station:—Ctenophoræ, Fierafer, Balanoglossus, Sipunculoidæ, Capitellidæ, Planariæ, Nemertineæ, Pycnogonidæ, Caprillidæ, and on several families of Algæ.

Three parts of the "Mittheilungen aus der zoologischen Station zu Neapel, zugleich ein Repertorium für Mittelmeerkunde" have been published, containing sixteen papers illustrated with many very carefully executed plates. Further parts are in active preparation.

It is, moreover, intended to publish the following works:—

"Fauna und Flora des Golfes von Neapel und der angren-

zenden Meeresgebiete." Folio. Yearly, 1 volume with 10–20 plates. The first volume is already in the press.

"Prodromus Faunæ Mediterraneæ." A selection from the whole zoological literature of short Latin diagnoses of the animals found in the Mediterranean, with their habitats and local names.

"Zoologischer Jahresbericht." This will contain short notices on the various memoirs and papers published in various countries on the subjects of zoology, development, and comparative anatomy. It is under the editorship of Prof. Carus, with the assistance of four collaborateurs in different countries. One volume will appear yearly.

Two naturalists have occupied the table hired by the Association, viz., Mr. Walter Percy Sladen and Mr. Patrick Geddes. Mr. Sladen has sent in a report on his stay and his work, which is appended. In this report he proposes "a means by which the table might be even more frequently occupied than it has been, and its sphere of utility thus extended, by suggesting to the consideration of the Committee that a further additional grant might be made by the Association, which would serve as a travelling fund. This might be apportioned in moieties say of 25*l.* to naturalists who desired to avail themselves of such assistance, and it is not improbable that many a student would by this means be enabled to participate in the advantages of the table at Naples, who might otherwise be deterred by the expense of the journey. The plan, extended or modified according to circumstances, is one adopted by several of the foreign bodies having tables at the Zoological Station."

Mr. Patrick Geddes worked at the station from February 26 to April 4. He "repeated and extended certain observations on echinoderm histology, and made experiments on *Bonellia viridis* and *Idotea viridis*, with a view of ascertaining the function of their (supposed) chlorophyll." The results of these studies are at present being published in the *Archives de Zoologie expérimentale* of M. de Lacaze Duthiers, viz., "Etudes sur le Chlorophylle animale," "Observations sur le Fluide periviscérale des Oursins."

Mr. Geddes also gained information on the working of the station, in the hope (now realised) of helping to found a zoological station in Scotland. This station is now in working order at Stonehaven.

Mr. Arthur Wm. Waters, who worked at the Association table last year, intends again to apply for the appointment to occupy it, with a view of extending his researches on the bryozoa of the Bay of Naples, already published in the *Annals and Magazine of Natural History*, 1879.

Your Committee think that the above particulars are sufficiently encouraging to induce the Association to renew the grant of 75*l.* for the ensuing year.

Report on the Occupation of the Table, by Mr. W. Percy Sladen.—In conformity with the requirements of the Committee of the British Association appointed in connection with the Zoological Station at Naples, I beg to submit the following report concerning my occupancy of the table which I had the privilege of using.

In availing myself of the opportunity of working at Naples, the main object which I had in view was that of studying the premature stages of the echinodermata, and more especially the growth-phases which intervene between the period when the pluteus is resorbed and that at which the adult characters are developed—the range and significance of these changes being very important and remarkable throughout the group. In addition to this chief object, it is scarcely necessary to add that there were numerous points in the morphology of echinoderms upon which, as a specialist, I was anxious to direct my attention, should time and opportunity permit.

I arrived in Naples on December 3, 1878, and remained there until February 17, 1879. During the greater portion of the time the weather was very inclement and stormy; in consequence of which the pelagic larval forms that I had hoped to have met with, by use of the surface-net, were driven to too great a depth, and owing to their microscopic proportions became thus altogether inaccessible. For this reason I was greatly disappointed in my expectations, and the material which I was able to obtain, in any way available for my projected investigations, was unfortunately very scanty; nevertheless several premature forms of considerable interest were procured, and these I am hoping still further to elucidate, before the end of the year, by finding, if possible, the corresponding and intermediate stages on our own coasts, and which will then enable me to work out the development of at least one or two forms completely. I also endeavoured to contribute somewhat to this subject by means of the artificial fertilisation of ova in several different families, but was always unsuccessful in keeping the *plutei* alive beyond a certain stage; whilst the fact that those thus raised in confinement were subject to very considerable abnormality in their development and present unnatural modifications which require much care and skill in elimination, in order to avoid error in subsequent deductions, greatly diminishes the utility of such observations as a direct method of embryological study, although they are not without value as furnishing some indication of the plasticity inherent in a given form.

Better success rewarded what I may speak of as desultory investigations upon the general structure of echinoderms. I may mention that I have in hand a contribution to the knowledge of *Pedicellariæ*, which I consider will throw light (if not entirely, at least in part) upon the functions of these obscure appendages. It was also my good fortune to discover in certain asteroids an hitherto undescribed organ, most probably performing sensorial functions; an account of which I hope to publish shortly, as soon as time permits me to work up the material which I collected more exhaustively than I was able to do whilst staying at Naples. In addition to the above I am also hopeful of furnishing a communication upon the premature anatomy of certain young echinoderms, for which purpose I was able to preserve and bring back with me several very good series of specimens.

The general success and continually increasing prosperity of the Zoological Station at Naples are now so fully known from the reports and various publications emanating from the institution itself, that it would be presumption on my part to offer any remarks in such a direction. I consider, however, that it is a duty for me to bear my individual testimony to the admirable arrangements which characterise the working of the station, and which conduce so greatly to the comfort of naturalists engaged in studying there. The daily supply of fresh material, the tank and aquarium accommodation for keeping the same alive, are highly satisfactory, and leave little to be desired; whilst in the way of ordinary laboratory apparatus and reagents no reasonable requirement is unprovided for.

I also desire to record my indebtedness for the genial kindness and the ever-ready assistance which I met with not only from Dr. Dohrn and the acting director Dr. Eisig, but the same friendly spirit of courtesy and help was accorded me without exception by every gentleman connected with the staff.

The utility of the Zoological Station being now so thoroughly established, and its reputation world-wide, it is unnecessary for me to allude to the fact, except to point out that the maintenance of such an undertaking is very costly, and that of necessity the results can only be continued by keeping up the funds. So much good work has already emanated from the station at Naples that the institution has a fair claim not only upon biological specialists, but on every one interested in the advancement of science. Upon such an argument, therefore, the Zoological Station is particularly worthy of the support of the British Association, even if its members were not (as many of them have already been) individual participants in the advantages which the station provides; and on this ground I would strongly urge the continuance of the grant usually made by the Association.

I would further beg to propose a means by which the table might be even more frequently occupied than it has been, and its sphere of utility be thus extended.

In conclusion I desire to express my cordial thanks to the Committee of the British Association for the privilege of using the table at their disposal. W. PERCY SLADEN

Exley House, near Halifax, August 2

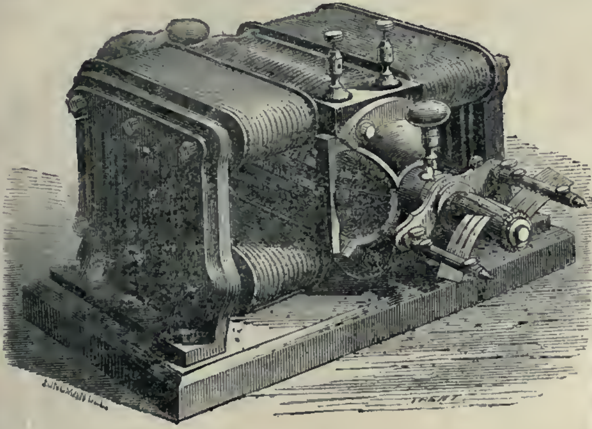
[A list of the naturalists who have worked at the Station, and of those to whom specimens have been sent during the past year, will be printed in the *Annual Report*.]

SECTION A—MATHEMATICAL AND PHYSICAL

On the Cause of the Bright Lines of Comets, by G. Johnstone Stoney.—Dr. Huggins and other observers had seen the bright lines of the carbon spectrum in the spectra of several comets. This established the fact that some compound of carbon was present in comets. In what had been hitherto written on this subject it had always been assumed that the compound of carbon was incandescent, and on that account emitted these bright lines. Mr. Stoney suggested, however, an alternative hypothesis which he believed to be entitled to much weight, viz., that these lines

were due to the sun's light falling upon the compound of carbon and rendering it visible, in the same way that light renders the moon, the planets, and other opaque objects visible, the vapour of carbon being opaque in reference to the particular rays, which appear as bright lines in its spectrum.

On Improvements in Dynamo-Electric Machines, by W. Ladd.—My object in this communication is to describe in a few words



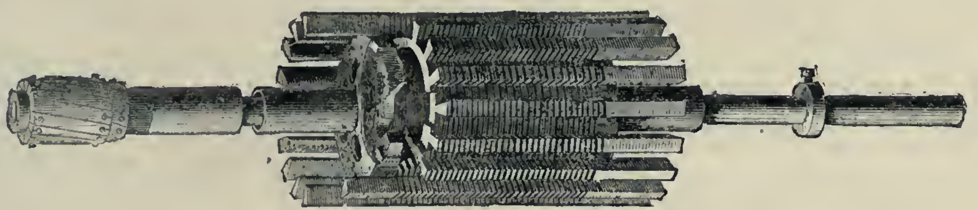
Weston's Dynamo-Electric Machine.

the peculiarities and improvements in the construction of Weston's dynamo-electric machine.

The Field Magnets.—The general appearance and arrangement of which may be seen in the illustration. The pole pieces are composed of iron plates, placed side by side in a mould, but separated a uniform distance from each other. The iron magnets, on which the wire is to be wound, are cast on to "lugs," or projections on the ends of the plates. The two cast-iron ends and uniting plates form one magnet; the upper and lower magnets are alike, and when joined together by the perforated vertical supports, the inner curved edges of the field plates embrace about two-thirds of the circle in which the armature is made to revolve.

The armature is built up of plates which are somewhat like a cogged wheel in shape (see illustration). These plates are stamped out of sheet-iron, and when mounted on the shaft are separated from each other at a uniform distance; the radial projections are then arranged in lines, so that the whole forms a very broad cogged wheel, or cylindrical structure having longitudinal grooves, with transverse spaces at regular distances. The longitudinal grooves are for carrying the wire, and it will be observed from the nature of the structure that the wire lies in channels three sides of which are iron; so that the mutual effect upon each other is increased as much as possible. The ends of the wires are connected to the field magnets and commutator in much the usual way, the currents travelling in one direction only. The commutator is fitted on a portion of the shaft which projects beyond the bearings. This admits of its easy removal and a new one being replaced in three minutes.

Another important feature in the construction is the arrangement for ventilation; the separation between the pole plates of the field magnets, the perforation in the vertical supports of the magnets, and the light frame-work of the armature, are all for this purpose. The air enters the centre of the armature, and is



Armature of Weston's Dynamo Electric Machine

driven out between the layers of wire through the spaces formed by the separated plates of the armature and the field magnets, and thus prevents any part from becoming unduly heated.

Machines of this description are made of various sizes and strengths, and give from one to sixteen lights in single circuit.

On the Direct Motion of Periodic Comets of Short Period, by Prof. H. A. Newton.—The periodic comets of short period, that is, the comets certainly seen at two returns, twelve or fifteen in number, have, all but one or two, small inclinations to the ecliptic; Halley's comet is an exception, being nearly retrograde in motion. Perhaps we may add the comet with which the November or Leonid meteors are connected (1866, 1), since it is, I think, almost certainly identical with the comet of 1836, and has an inclination of about 163°.

The direct motion of the periodic comets seems to give them a peculiar relation to the solar system, even suggesting for them an origin common in some way with the origin of the planets. The other comets apparently come to us from outside the solar system, and if in any cases they are permanent members of the solar system, they have become such by the perturbations of the planets. Can it be that such perturbations have also forced the periodic comets into their present orbits?

The ordinary perturbating forces are small, and would almost as frequently increase as diminish the inclination of a comet's orbit. To every comet passing on one side of a planet, and so having its inclination diminished, there should be among an indefinitely large number of comets a second comet passing on a symmetrically opposite side, and having its inclination increased. But if we state the question properly, we get a different answer. If an indefinitely great number of comets approach and pass a large planet, and if the directions and lines of motion are uniformly distributed, some of those coming near to the planet will be turned into orbits of short period. Considering only the orbits thus affected, will they have in general small inclination? I find that they will, and that therefore we are not required, because of their different motions, to consider the periodic comets of short period as different in genesis from those of long period, or from those having parabolic orbits.

The conclusion suggests the possibility of a common outside origin to the periodic comets and the asteroids. It also suggests the possibility of an outside origin for the matter that makes up the zodiacal light, since it would explain the near coincidence of the plane of this mass with the ecliptic, notwithstanding its outside origin.

If, in addition, we may admit a like origin for the satellites, and even for some of the smaller planets, we are rid of the difficulty that seems to me insuperable, of supposing, as is usually done, that the very small bodies become solid from a nebulous state in the immediate presence of the sun and large planets.

On Self-acting Intermittent Syphons and the Conditions which Determine the Commencement of their Action, by Rogers Field, B.A.—In an extensive series of experiments which the author tried some years ago on syphons, with their outer legs dipped in water, he was much puzzled by finding that the quantity of water necessary to put a syphon of given size into action varied in the most unaccountable way at different times. The only difference that could be perceived between the cases in which the syphon started and those in which it did not start was, that in the former case air-bubbles escaped freely at the mouth of the syphon, whereas in the latter case, under apparently the same conditions, very few bubbles came out. At last the idea suggested itself of making a portion of the syphon in glass, so as to see what was going on inside the pipe, when the course of the irregularity was at once discovered. Sometimes the water which ran over the bend adhered closely to the sides of the pipe, at other times a portion of it would fall more or less clear of the sides. When the water adhered to the sides it produced very little effect in displacing the air, so that only a small quantity of air was driven through the water at the mouth of the syphon. When on the other hand the water fell clear of the sides, it produced a great effect in displacing the air, and large bubbles of air at once escaped from the mouth of the syphon.

The investigation was pursued further by producing artificial irregularities in the pipe, and it then appeared that the more completely the water could be thrown clear of the sides of the pipe, the greater effect it produced in expelling the air and starting the syphon.

The author applied this and other principles in his intermittent syphon, of which a working model was exhibited, and which was illustrated by diagrams. Self-acting syphons have been used in emptying vessels for measuring water, as in Osler's and Bickley's self-recording rain-gauges; and the syphon described might be so employed and also in a more practical manner, such as for flushing sewers by water which usually runs to waste.

Mr. W. E. Ayrton read a paper by Dr. Muirhead *On the Constancy of the Capacity of Certain Accumulators*, and a note thereon by Mr. C. Hockin. The latter communication contained an account of observations which were first begun with the object of redetermining the capacity of certain condensers employed in the testing of cables, and in terms of which the capacity of many cables now submerged have been recorded and published. In consequence of these papers a committee was appointed by the Association, on the recommendation of Section A, for the purpose of deciding upon an authoritative standard of electrical capacity.

Prof. G. Forbes made some remarks upon *The Bursting of Firearms, when the Muzzle is closed with Earth, Snow, &c.*—This well-known fact was explained in a simple manner. If the charge moved slowly, of course very small pressure of air would drive out the obstacle, which offered a very small resistance; but in practice the charge travelled with a speed of more than the velocity of sound. The mathematical investigation showed that the pressure generated with a plug of the density of air is $7\frac{1}{2}$ tons. The complete investigation is to be found in the *Proceedings* of the Royal Society of Edinburgh.

The Section devoted Saturday as usual to the mathematical papers, which were not so numerous as they have been in recent years.

Mr. H. M. Jeffery gave an account of his work *On Plane Class Cubics with Three Single Foci*, which concluded his enumeration of curves of the third class; and Mr. W. H. L. Russell communicated a theorem *On Linear Differential Equations*.

Mr. J. W. L. Glaisher gave an account of *Some Enumerations of Primes of the Forms* $4n + 1$ *and* $4n + 3$, referring to the investigations of Prof. Tchebycheff, who had shown that primes of the form $4n + 3$ were more numerous than those of the form $4n + 1$, the difference in the numbers of primes of the two forms up to a certain large limit x being for certain values of x of the order $\frac{\sqrt{x}}{\log x}$. Mr. Glaisher also communicated an elementary method of summing the series

$$\tan^{-1} x^{2n} + \tan^{-1} \frac{x^{2n}}{2^{2n}} + \tan^{-1} \frac{x^{2n}}{3^{2n}} + \&c.,$$

and similar series, and also some formulæ in elliptic functions.

Mr. A. J. C. Allen read a paper *On some Problems in the Conduction of Electricity*, the principal object of which was to solve the problem of the conduction of electricity in a spherical current sheet, the electricity being introduced and carried off from the sheet at any number of points, called electrodes; and also to do the same for certain finite portions of a spherical sheet, bounded either by current or equipotential lines, the motion being in all cases steady. This was effected by means of a theorem, which was then applied to deducing solutions for a number of finite areas on the sphere. The case of one source and an equal sink on a complete sphere was discussed in detail, and the current and equipotential lines shown to be two systems of small circles. A similar theorem, though not quite so universal in its application, was shown to hold for a sheet in the shape of a circular cylinder. The paper concludes with a solution in singly infinite series of the problem of the conduction of electricity in a plane area, bounded by two concentric circles, and also in that bounded by two concentric circles and two radii, meeting at an angle $\frac{\pi}{n}$ (n integer).

SECTION B—CHEMICAL SCIENCE

Notes on Recent Spectral Observations, by J. N. Lockyer, F.R.S.—The following results have been obtained by the method recently described to the Royal Society (*Proc.* R.S., vol. xxix. p. 266 :—

1. Carefully distilled sodium condensed in a capillary tube, and placed in the retort, gives 20 volumes of hydrogen.
2. Phosphorus carefully dried gives 70 volumes of gas, chiefly hydrogen, which, however, is not PH_3, although it gives some of the lines of phosphorus. It is not PH_3, because $CuSo_4$ is not touched by it.
3. Magnesium carefully prepared by Matthey is magnificent in its colourings; we get first hydrogen, then the D line [not sodium, for the green line is absent], then the green lines of magnesium, (*b*) then blue line, then various mixtures of all of them, as the temperature is increased, D being always the brightest, 2 volumes ($\frac{1}{2}$ *cc*) of hydrogen only were collected.
4. With gallium and arsenic the pump always clicks, indicating that no gas is given off.
5. From sulphur and some of its compounds there is always So_2.
6. From indium, hydrogen comes over before heating.
7. Lithium gives 100 volumes of hydrogen.

The conditions of the experiments have always been the same, the only variable being the substance. The volumes stated are those generally obtained; almost all experiments are ended by the cracking of the tube.

On large Crystals of Mercury Sulphate, by Philip Braham.—Mr. Braham exhibited crystals which had taken over two years in forming, and were due to the presence of a trace of nitric acid in the sulphuric acid in which they were formed.

On the Manufacture of Crucible Steel, by Henry S. Bell, F.C.S., &c.—The manufacture of crucible steel is one of the most important industries connected with the town of Sheffield, which boasts of not less than 120 firms engaged in the production of this material. Notwithstanding the enormous output of steel by the Bessemer and Siemens-Martin processes, this kind of steel is unrivalled for the manufacture of the finer varieties of cutlery and edged tools, &c. A brief outline of the process itself is as follows:—The most of the iron employed for this purpose is imported into this country in the shape of bars from Sweden, where it has been smelted from very pure iron ores, in a blast furnace, by the aid of charcoal, and subsequently puddled to free it from impurities.

The first operation to which it is subjected, is that known as the cementation or converting process, the object of which is to combine a certain quantity of carbon with the iron; this operation is performed in a furnace of peculiar construction, where the iron and charcoal are packed together in air-tight chests or converting pots, subjected to a high temperature short of the fusing point of iron, where it remains for a matter of three weeks.

After the conversion, when the pots are cold the bars are taken out and found to be covered with blisters, hence it is termed blister steel. In consequence of the various theories proposed to account for this peculiar formation, the writer was induced to make a series of investigations. For this purpose he was kindly furnished by Messrs. Seebohm and Dieckstahl, of the Dannemora Steel Works, with some samples of this blister steel, various portions of which he submitted to analysis, the results of which showed a marked increase of silicon where the blisters occurred.

On inspecting one of these bars of blister steel, it is found that it has undergone both a physical and a chemical change.

The iron has now assumed a crystalline structure, and has chemically combined with a certain amount of carbon. This latter change commences on the exterior, and extends itself to the interior of the bar, if the process be continued sufficiently long, thus showing that carbonic oxide never penetrates into the centre of the bar, until the whole is converted into steel.

The writer is indebted to the kindness of the above-mentioned firm for a sample of bar iron, before and after conversion, in order to ascertain the exact chemical change that took place during the process. The following are the results obtained:—

	Before Conversion	After Conversion
Fe	99·471	98·603
C	0·352	1·250
Si	0·050	0·035
S	0·027	0·022
P	0·025	0·018
Mn	0·075	0·072
	100·000	100·000

The decrease in impurities appears greater than it really is, owing to the fact that the bar itself has increased in weight by the addition of carbon.

One remarkable fact is that, after the conversion of the iron, a quantity of the charcoal, in the converting pots, is found in a pulverised state, so as to be unfit for further use.

Some of this waste charcoal the writer has examined, and from one sample, by the aid of a magnet, he succeeded in extracting 5 to 6 per cent. of iron scale, and small pieces of steel, these on being treated with dilute hydrochloric acid, evolved considerable quantities of sulphuretted hydrogen; in one case he estimated the quantity of sulphur, and found it to contain as much as 1·25 per cent. of this element.

The steel is now broken up into small pieces and melted in crucibles, and cast into ingots. These are sent to the forge, where they are heated and rolled. In this part of the process the chief difficulty with which the silter has to contend is the porous or "honey-combed" structure of the steel.

One of the characteristic features relied on by practical men as indicating the quality of a piece of steel is the appearance of its fracture; but this is by no means an infallible test, as the fineness or coarseness of grain can be produced by mechanical treatment or chemical means.

The characteristic property possessed by steel is its capability of being hardened and tempered. The temper of cast steel may be said to range from 0·75 to 1·50 per cent. carbon. The temper of steel is an important question in connection with the purpose for which it is required; thus a steel containing 1·50 per cent. of carbon is the class employed for razors. 1·25 per cent. is that known as "tool temper." Steel containing 1·00 per cent. carbon is termed "chisel steel," and this temper is extensively used in the arts.

The latter part of the paper is occupied with the consideration of the manner in which bodies such as carbon, silicon, sulphur, phosphorus, and manganese, affect the quality and mechanical properties of the steel.

A Lecture Experiment in Illustration of the Hollway Process of Smelting Sulphide Ores, by Alfred H. Allen.—By causing oxygen gas to bubble through molten antimony sulphide contained in a V-shaped piece of combustion-tube, combustion takes place with such rise of temperature as to soften the glass, while a sublimate is obtained of antimonious oxide, and sulphurous acid gas is evolved. The sublimate is collected in an empty globe, and the sulphurous acid is absorbed by passing it into a large vessel containing lumps of wood-charcoal. At the conclusion of the experiment the contents of the combustion-tube may be poured out, when a button of metallic antimony free from sulphur is obtained.

By passing oxygen over lumps of pyrites contained in a heated combustion-tube, vivid combustion takes place, much free sulphur sublimes, and sulphurous acid gas is obtained and absorbed as before described.

On the Presence of Nitrogen in Steel, by Alfred H. Allen.—The author made some preliminary experiments on the subject in 1872, but has only recently obtained any definite results. The method adopted has been to dissolve the steel in hydrochloric acid, by which means any combined nitrogen may be presumed to be converted into ammonia. The solution obtained was then distilled with excess of lime, and the distillate examined for ammonia by Nessler's method. The employment of this extremely delicate test enabled the author to operate on a much smaller quantity of steel than was employed by previous investigators. Very special precautions were taken to obtain the hydrochloric acid and other materials free from any trace of ammonia or nitrous compounds, and the air was entirely expelled from the apparatus before commencing the operation. The hydrogen evolved was freed from any traces of ammonia by passing it through a tube filled with glass beads moistened with hydrochloric acid. It was proved by blank experiments that no source of ammonia existed in the reagents or apparatus.

When absolutely pure materials were used, and every precaution taken to get rid of the contained air and other sources of error, the addition of Nessler's solution to the liquid obtained on distilling with lime caused a very marked yellowish-brown coloration.

The author then gives the amount of nitrogen determined by his method in different varieties of steel.

In order to obtain ammonia in quantity sufficient for its recognition by other reactions than that with Nessler's test, the following plan was employed:—

Steam, generated by boiling water in a flask, was passed over a considerable quantity of steel borings contained in a combustion tube which was bent beyond the furnace, and prolonged so as to form the inner tube of a Liebig's condenser. To the further end, a tube filled with glass beads and furnished with a glass stopcock was attached. A rapid current of steam was driven through the apparatus for a considerable time to expel every trace of air. On condensing the steam it was found free from any trace of ammonia. The steel borings were then heated to redness by a combustion furnace, and a rapid current of water passed through the condenser. The condensed steam, when tested by Nessler's solution, was found to contain abundance of ammonia, which did not diminish in amount till the borings were almost entirely oxidised. On redistilling the condensed steam, a distillate was obtained, having a distinctly alkaline reaction to litmus paper, and on treating it with hydrochloric acid and platinic chloride a sensible amount of yellow precipitate was obtained, having the characteristic crystalline form of ammonium chloroplatinate. The amount found was larger than could possibly have been produced had the whole of the nitrogen of any residual trace of air been converted into ammonia.

The author regards the results now recorded as preliminary merely, and proposes to extend the research to various classes of steel and iron, and especially to such specimens as have been found to possess anomalous characters. Of these, the evolution of ammonia from freshly fractured surfaces is the most striking.

On the Separation of Phosphorus in Steel Manufacture, by Thomas Blair.—He said the complete removal of phosphorus from pig-iron is of the utmost importance to this country, as the greater portion of ores raised and iron made here is unfit for the manufacture of steel by the Bessemer processes. A history of the various processes made use of for the purpose were examined in detail, especially the processes of Messrs. Bell, Thomas, and Gilchrist. The writer concluded that this latter process was in a fair way to succeed commercially, and that it seemed only necessary to effectually remove a few remaining difficulties.

SECTION C—GEOLOGY

On the Coal Fields and Coal Production of India, by V. Ball, M.A., F.G.S., of the Geological Survey of India.—The coal-bearing rocks of Peninsular India are all included within the limits of the great series of plant-bearing rocks to which the term Gondwana has been applied, and they are further limited to two groups of rocks which occur in the lower portion of that series.

By some authorities the age of these Gondwana rocks is supposed to be equivalent to that of the European formations which range between and include the lower oolite and the base of the trias (Buntsandstein). By others the lower measures, including the coal, are believed to be palæozoic. The author proceeded to give an outline of the recent discussions on this subject, referring particularly to Mr. W. T. Blandford's judicial summary of the evidence in the lately issued "Manual of the Geology of India."

The distribution of the coal-bearing areas was then pointed out on a series of maps which were exhibited, and the number of distinct coal-fields was stated to amount to about thirty. Some details were then given regarding these fields, of which five only are worked at present, namely, Ranigunj, Kurhurbali, and Daltongunj in Bengal, and Mopani and Warora in the Central Provinces.

The total area of the Indian coal-fields is estimated by Mr. Hughes at upwards of 30,000 square miles. Three countries alone contain larger areas, viz., the United States 500,000, China 400,000, Australia 240,000.

In quality the Indian coals are inferior to the average of English and Australian; but they are capable of accomplishing good work in locomotives, and for this purpose they are largely employed on the main lines of railway in India—Indian coal mixed in equal proportion with English.

The author proceeded to give further details as to the quality of the coal, stating that the anthracite varieties were rare, the general character being bituminous and the structure laminated—bright and dull layers alternating.

In round figures it may be stated that at present 1,000,000 tons of coal are consumed in British India *per annum* in locomotives and factories, the quantity employed in the form of coke for domestic purposes being inconsiderable; and that of this 1,000,000 tons, about one-half is raised from Indian mines, the other coming from England, France, and Australia.

On the Keuper Beds between Retford and Gainsborough, by F. M. Burton, F.G.S.—After describing the general position of

the beds in relation to the triassic system, and remarking on the absence of the upper mottled sandstone, as well as the "Muschelkalk," in this part of England, the author described the various strata of the district, as shown on the line between Retford and Gainsborough, and pointed out the want of any division in the beds of the lower keuper sandstone, as in other localities, and the absence of any boundary line between this series and the "red marls" above.

On a Northerly Extension of the Rhætic Beds at Gainsborough, by F. M. Burton, F.G.S.—At the meeting of the British Association at Nottingham in 1866, the author announced the discovery of beds of the rhætic age at Gainsborough, a full account of which will be found in the *Quarterly Journal* of the Geological Society for 1867. These beds occur to the south of Gainsborough, on the Great Northern line between Doncaster and Lincoln, and were discovered through the lowering of the gradients of that line in 1866. The author has since found them in a cutting of the Manchester, Sheffield, and Lincolnshire Railway at Blyton, about five miles to the north of Gainsborough, where they must have been exposed since the making of that line in the year 1848, though hitherto they have remained unrecorded.

The Age of the Penine Chain, by E. Wilson, F.G.S.—In this paper the author combated the generally accepted view of the post-Permian origin of the Penine chain, and contended for a pre-Permian upheaval. In support of this opinion the following facts were cited: The Yorkshire coal-basin was admittedly pre-Permian, for north of Nottingham the magnesian limestone everywhere overlaps the coal measures; but the axis of this basin is parallel with the Penine chain, and was evidently determined by the same series of movements that upraised that chain. The Permians disappear on the west in approaching the Penine chain; in this direction also the marl slates attenuate, and these and the magnesian limestone become more sedimentary, as if approaching a margin. Mountain limestone pebbles occur in Permian breccias on one or both sides of the Penine axis. Many fragments of carboniferous rocks occur in lower Bunter sandstone (breccias) on the borders of Notts and Derbyshire; but the author finds no fragments of Permian rocks in these breccias. No outliers of Permian rocks are found at any distance west of the magnesian limestone escarpment between Nottingham and Northumberland. The character and succession of the Permians on the two sides of the Penine chain are very dissimilar.

On Geological Episodes, by J. F. Blake, M.A., F.G.S.—Geological nomenclature was first founded on the theory of universal deposits; then the idea of lateral changes was introduced, with the necessary misuse of lithologically descriptive names; ultimately all deposits were seen to have their boundaries. Beds deposited in distinct areas can thus be proved only homotaxial, and these are by no means necessarily synchronous. The object of this paper is to show that a somewhat similar principle ought to govern all our geological classification. A single area is defined to be one over which we can trace one or more related formations consecutively, and which formations contain identical characteristic fossils. Deposits in single areas may be compared as to time and divided into life zones; but these in different areas are homotaxial only. In each single area the outlines and characters of the several deposits must first be determined and denoted accordingly.

In studying any group of rocks in a single area it is seen that some members have a much wider range than others. Such differences in range are accompanied by marked differences in character and point to differences in the circumstances of deposit. The wide-spread formation indicates uniform changes of level over the area and a mixture of deposits—such circumstances may be called normal. But mere local changes may bring more restricted areas into peculiar physical conditions. Such local changes may be called "geological episodes," and they will result in the formation of deposits of marked character easily distinguishable from the normal.

The first point is to determine the characters by which an episodal deposit may be differentiated from a normal one. The supreme test is that derived from its definition, *i.e.* its local development; but if it be very small, it may be insignificant; if relatively very large, the distinction may be of no consequence. As a rule argillaceous rocks are normal, and arenaceous and calcareous episodal; but this is by no means universal. When the normal formation of a period is determined, the episodes are marked by their differing mineral nature. The two kinds of deposits may also be determined by the nature of their fossils, after we have first discovered what kinds of fossils are usually episodal. For this purpose those fossils which are found in all kinds of rocks, and therefore appear to have been indifferent as to their physical surroundings, may be called *invariant*, and those found only under particular conditions, and which change their locality as these conditions change, *covariant*. Invariants only are suited for zonal classification; covariants are characteristics of episodes. A table is drawn up showing the classes, families, and genera which may be covariant, according to the imperfect observations of the past. The chief covariants are a few foraminifera—the sponges—a large number of hydrozoa and actinozoa, some crinoids, the blastoids, a few lamellibranchs, and at least half the gasteropod families.

The main proposition is that *similar, but distinct episodes, in a normal series of strata are neither necessarily nor probably of the same age.* The true method of geological classification is therefore to arrange only the normal deposits in a series by their stratigraphy and their invariant fossils, while the episodes are put in their place as such.

These doctrines applied to British strata yield the following results: No episodes are recognised in Cambrian or pre-Cambrian rocks. In the lower Silurian, the Durness limestone, the Llandeilo flags, the Bala limestone and the Caradoc sandstone, and the May Hill and Llandovery beds are characterised as such. Hence the term "Caradoc" is inapplicable as a name for the normal portion of the series. The "Colonies" of Barrande may be episodes recurrent on the same area. In the upper Silurian, the Wenlock and Aymestry limestone, the Denbigh grits, and tilestones are episodes. The carboniferous series present us with the Coomhola grits, Burdie House limestone, Millstone, and Pennant grits, while the mountain limestone is merely a gradually changing normal deposit. The episodes of the Permian are the fossiliferous limestone and underlying marl slate. The absence of the Muschelkalk from England is not regarded as due to its being an episode, but to our deposits as a whole being formed in a distinct area, the true episodes of the period being the Hallstadt, St. Cassian, and Dachstein beds. The lias is remarkable for its great freedom from episodes, which accounts for the success of its zonal classification, the only exceptions being the Sutton series, and some of the middle lias rock beds. The lower oolites, on the contrary, are almost entirely episodal, none of the beds having a wide range. The Yorkshire deposits were formed in a distinct area, and may cover the period of the great oolite as well as the inferior oolite, the deposits supposed to connect them with the latter being episodes. The rocks above the Cornbrash formed one connected series, as recognised by all German writers and some French, in which the Kelloway rock, the Corallian, and the Portland rocks are well marked episodes in this country. It is therefore suggusted that the term "middle oolites" should be abolished from the classification of British strata, and the whole be known as upper oolites. The various episodes in this series on the Continent and in England will never be truly located until their real character is seen, and it has been by the study of these rocks that the doctrine of episodes has been suggested.

In the cretaceous series the wealden, the Tealby series, and parts of the lower greensand are episodal, the ironsands being the nearest approach to a normal formation. The upper greensands are also episodes; but the chalk, though calcareous, is normal.

The lower tertiaries, like the lower oolites, scarcely present any normal deposits, the London clay being, though argillaceous, episodal in character.

In the result, the series of sedimentary rocks should be represented not by so many parallel lines, but in many cases by lenticular masses, whose age is denoted by their position—according to a table which presents their true character. It is urged, therefore, that the names proposed—or else some better—be used to distinguish the different kinds of strata and fossils, in order to give definition and importance to truths which must have long been floating in the minds of geologists.

The Surface Rocks of Syria, by J. Perry.—The paper was suggested by an examination of the sandstone quarries at Baalbec. The rock is composed of a mixture of the particles of limestone from the coast, and drift-sand. The mixture is consolidated layer by layer, and fresh rock of the same nature is now in process of formation. The author explained how the consolidation is produced by water dissolving the particles of carbonate of lime and by alternations of temperature. The author then gave some explanation of the veined and apparently cracked appearance of certain limestones.

On the Bone-Caves of Derbyshire, by Prof. W. Boyd Dawkins, M.A., F.R.S.—The first cavern discovered was that at Wirksworth in 1820, accidentally come upon in the workings of a lead-mine. Elephants, rhinoceri, &c., were found there. In 1875 the Rev. J. M. Mello explored the caves at Creswell Crags, which have yielded most important results. Amongst the bones found are those of hyæna, bison, reindeer, lion, hippopotamus, and bear, together with implements of flint and chert, and an engraved bone showing a sketch of the horse. The caves yield evidence of improvement in the manufacture of implements in succeeding dates. In 1876 Prof. Dawkins and Mr. Rooke Pennington explored the Windy Knoll, near Castleton. From the mode of occurrence of bones here, it seems clear that the bison was a summer or late-spring resident; the reindeer a winter one. A cavern near Matlock Bath was explored in 1879.

There is no evidence as to the age of these caverns; nothing to show that they existed before or during the glacial period. The author deprecated any attempt to place before the public a greater definiteness as regards the date of geological events than the facts warrant.

On Ammonites and Aptychi, by C. Moore, F.G.S.—The author gives evidence which renders it probable that the aptychus is not an operculum. It often occurs associated with numerous minute eggs; and the author suggests that, with the siphuncular tube, it probably represents an ovarian sac.

On the Classification of the British Pre-Cambrian Rocks, by Dr. H. Hicks, F.G.S.—The author divides the pre-Cambrian rocks into four groups under the following names, in ascending order:—1. Lewisian; 2. Dimetian; 3. Arvonian; 4. Pebidian.

1. *The Lewisian.*—So named by Sir R. Murchison to indicate the crystalline rocks of the Hebrides and north-west Highlands of Scotland, is retained to indicate the oldest group at present recognised in Britain, and largely developed in the Hebrides. It is found also in parts of the Malvern Chain, the north-west of Ireland, and possibly also in Anglesey. The prevailing rocks in this group are massive gneisses, in which hornblende and felspar are the chief ingredients, and quartz chlorite and mica but sparingly present. They are usually of a dusky red, grey, or dark colour. Sometimes almost a pure hornblende rock is found. The strike in these beds is usually east and west, or some point between that and north-west and south-east.

2. *The Dimetian.*—This group is largely developed in Wales, as at St. Davids, Caernarvon, Rhos Hirwain, and Anglesey. It has been found by Dr. Callaway in Shropshire, and I have recently seen it with him also in the Malvern Chain, especially in the Worcester Beacon. I noticed it also, last year, in large development at Ben Tyn, Loch Maree, and near Gairloch, in Ross-shire, as well as at several other points in the north-west Highlands of Scotland. The prevailing rocks in this group are granitoid and quartzose gneisses with pinkish, flesh-coloured, or white felspar, and with limestone, micaceous, and occasionally chloritic and hornblendic bands. Brecciated beds also occur, in which bits of the older Lewisian gneiss are sometimes found. The strike is generally north-west and south-east, or from this to north and south. It evidently overlies the Lewisian unconformably in the areas where both have hitherto been found associated; and its highly quartzose character and lighter colour generally, are in marked contrast to most of the members of that group.

3. *The Arvonian.*—At the last meeting of the British Association I mentioned, for the first time, the discovery, or rather the separation, of this group. It is largely developed in Pembrokeshire and Caernarvonshire. It occurs also in Anglesey and Shropshire, and I have recently found it at the base of the Harlech mountains. I have seen masses of it also from the Orkneys, and it probably occurs both in the Western Islands and in the Grampians of Scotland. It is the great hälleflinta group of the Swedish geologists, and the petro-silex group (Hunt) found so largely developed in North America. It is chiefly made up of quartzo-felspathic rocks, sometimes porphyritic, frequently brecciated, and of compact quartzose rocks or hälleflintas, which on microscopical examination have the appearance of incipient gneiss. The strike is usually about north and south, and it overlies the Dimetian unconformably.

4. *The Pebidian.*—This being the newest group in the pre-Cambrian rocks, is the least altered in character, and most nearly approaches in strike to the overlying unaltered or Cambrian rocks. It resembles that group in many of its rocks, and on that account was for a time supposed to be identical with it, only that it had undergone alterations. Now we know that it underlies the latter unconformably, and that the apparent similarity in character is to be attributed to the fact that most of the Cambrian rocks were derived from the denudation of this group. That it was also in a high state of alteration before the Cambrian rocks were deposited upon it is evident from the fact that an abundance of pebbles and masses of it occur in the conglomerates at the base of the Cambrian. It consists for the most part of chloritic, felspathic, talcose, and micaceous schistose rocks, alternating with massive and slaty greenstone bands, dolomitic limestone, turpentine, lava-flows, porcellanites, breccias, and conglomerates. It is traversed also frequently by dykes of granite, dolerite, &c. It is a group of enormous thickness, and is largely distributed over Great Britain. It occurs in many parts of Wales, in Shropshire, and in Charnwood Forest. I found it also last year in the north-west of Scotland, and I have seen specimens of it collected by Mr. Jas. Thomson and others from Islay, and others of the Western Islands. Dr. Hunt recognised it also along the Crinan Canal, and in the vicinity of Lough Foyle in Ireland. It is probably represented in America by the Huronian group. The prevailing strike is north-north-east to south-south-west, or from this to north-east and south-west. The conglomerates at its base are largely made up of masses derived from the Arvonian, and, at most of the points examined, it is undoubtedly unconformable to that group.

SECTION D—Biology

Department of Anatomy and Physiology

On a Visual Phenomenon and its Explanation, by Wm. Ackroyd, F.I.C. Abstract of the paper (A).—Visual phenomena are of general interest and are often described, but seldom explained. The phenomenon in question may be seen under the following circumstances. Face the breeze and without winking allow a small rain-drop to fall on the surface of the cornea, all the while keeping your gaze fixed on a lamp light some hundred feet away. As the raindrop alights on the cornea, several rings of light appear to surround the luminous source and *they gradually contract in diameter*. Explanation:

In sunshine, the moving ring-crest of water, produced by dropping a pebble into a still and shallow pool projects a ring of light on the bottom, which gradually increases in size. The moving ring-crest, by its refractive action, produces a hollow cylinder of rays of ever-increasing diameter, and we see a section of it on the bottom of the pool. The rain-drop falling on the cornea spreads out on its surface in several ring-crests, and would similarly produce a series of outward travelling rings of light were it not for the combined action of the refractive media of the eye. Under the influence of these two hollow cones of light are formed within the vitreous humour directly upon impact of the raindrop. The first of these has for its base a small circular area of the hind surface of the lens, and its prolongation; the second cone has the retina for its base. As any individual ring-crest spreads out on the cornea, the first cone increases in size, the common apex advances towards the retina, and consequently the section of the second cone projected on to the retina decreases in size and appears as a contracting ring of light.

Department of Zoology and Botany

Prof. Ray Lankester read a paper, *On a Case of Disputed Identity—Haliphysema.*—The different views of Haeckel and others on this remarkable form were discussed, and its history traced. Prof. Ray Lankester, from a careful examination of recent specimens forwarded by Mr. Savile Kent, has no hesitation in stating that it is not a sponge but a curious rhizopod-like amœba with a test of sponge spicules curiously constructed like that of a caddis worm.

Prof. Westwood, M.A., read a paper *On the Insects which Injure Books.* Referring to an address delivered by Dr. Hagen, on July 2, 1878, before the American Library Association on the same subject, Prof. Westwood passed in review the life-history of the different species of insects which have been found to destroy books and printed papers, several of which were not noticed by Dr. Hagen. The caterpillars of the moth *Aglossa pinguinalis*, and also of a species of *Depressaria* often injure books by spinning their webs between the volumes and gnawing small portions of the paper with which to form their cocoons. A small mite, *Cheyletus eruditus*, is also found occasionally in books kept in damp places. A very minute beetle, *Hypothenemus eruditus*, forms its tiny burrows within the binding of books.

Lepisma saccharina also feeds on paper, of which a very curious example was exhibited of a framed and glazed print of which the plain paper was eaten whilst the parts covered by the printing ink were untouched. White ants, Termitidæ, are a constant source of annoyance in warm climates; and Prof. Westwood also noticed the ravages committed by the cockroaches, *Blatta orientalis*.

The insects that do the greatest injury are *Anobium pertinax* and *A. striatum*, commonly known as the death watches, burrowing through the books, even, it is recorded, drilling through 27 folio volumes.

Various remedies for the destruction of these insects were mentioned and especial notice was directed to a "Report of the Commission appointed to inquire into the Decay of Wood-Carvings, and the Means of Preventing and Remedying the Effect of such Decay," issued by the Science and Art Department in 1864.

Prof. Westwood then detailed the various remedies proposed, as washing with solution of corrosive sublimates in alcohol, exposing the books to the vapour of benzine, or carbolic acid, or hydrocyanic acid, or fumigating with burning sulphur. Placing the volumes under the exhausted receiver of an air pump for an hour, has been found successful by Dr. Hagen.

The Occurrence of Leptodora in England.—Sir John Lubbock called the attention of the Section to the occurrence in England of Leptodora, a very interesting crustacean first found in deep lakes abroad, and more recently in a reservoir near Birmingham. Like many marine organisations it was as transparent as glass. This rendered the creature less conspicuous to its foes. Like other animals of the same group it laid two kinds of eggs. The young at first were quite unlike their parents, so unlike that they had been thought to be a distinct species. Sir John then entered into a description of the little animal, and by means of sketches illustrated the peculiar functions of the different organs, pointing out the difference of the organs in male and female.

On the Homologies of the Cephalopoda, by J. F. Blake.—The flexure of the intestine in Cephalopoda and Pteropoda is "pedal," and that of other Odontophora, "cephalic;" and the body of a cephalopod must be placed with the mantle cavity horizontal for comparison with a gastropod. The arms are not homologous with the foot, but form an "antivelum." The labial and tentacular processes, and not the individual tentacles of a Nautilus are shown to be homologous to the arms of an Octopod. The hood is associated with the aptychus of the Ammonite, the shell of an Argonaut, and the neckplates of a Sepia. The Ascoceras is cited to show the relations of the sepia-bone to the nautilus shell.

On Cyclops, by Marcus M. Hartog, M.A., B.Sc.—The nervous-cord of Cyclops is essentially copepodan in type, it is not dilated into special ganglia, and contains no cellular elements beyond the third thoracic segment. It bifurcates in the second abdominal segment, and the branches terminate in the furca. The sensory and motor nerves appear to be wholly distinct, the latter coming off at a higher or deeper level. All the sensory nerve-fibres pass through a bipolar ganglion cell near their distal termination. Minute rounded spaces in the hypoderm, especially one at the base of the last thoracic limb, appear to be auditory organs. Respiration in Cyclops is entirely anal.

On Mimusopeæ, a Section of the Order Sapotaceæ, by Marcus M. Hartog, M.A., B.Sc.—In this paper the genus Dipholis is merged in Bumelia, and the genera Imbricaria, Labramia, and Muriea in Mimusops: a review of the deferential characters hitherto relied on showing their inadequacy from every point of view—even convenience.

On Fruits and Seeds, by Sir John Lubbock, Bt., V.P.R.S. M.P.—Sir John commenced by calling attention to the difference presented by seeds, some being large, some small, some covered with hooks, some provided with hairs, some smooth, some sticky, &c., and after observing that there were reasons for all these peculiarities, proceeded to attempt to explain some of the more striking. In the first place, he said, many seeds required protection from birds and insects; hence the shells or husks of the beech, Spanish chestnut, horse chestnut, walnut, &c. In some cases, as in the common herb Robert, the calyx, or outer envelope of the flower opens, when the flower expands, and closes over the seeds when the flower fades, and opens again when the seeds are ripe. In other cases the flower-stalk changes its position. Thus in the dandelion, it is upright when in flower, lies close to the ground after the flower has faded, and rises again when the seeds are ripe. In the cyclamen again, the flower-stalk curls itself up into a spiral after the flower has faded.

He then called attention to the modes of dispersion by means of which seeds secure a sort of natural rotation of crops, and are also in other cases enabled to rectify their frontiers. Some plants actually throw their seeds. Thus in the common cardamine, the outer membrane of the pod becomes very tense, and when ripe, at the least touch it gives way at the base, and curling up with a spring throws the seeds three or four feet. The common geraniums also throw their seeds, and so do some of the cucumbers, but in these cases the mechanism is different. He then described the curious "elaters" of the equisetums, and other means of dispersion possessed by seaweeds, and other low organised plants. Among the higher plants, the seeds are in many cases transported by the wind. Sometimes, indeed, the whole plant is thus blown about, as in the case of the celebrated rose of Jericho, an annual inhabiting the sandy plains of Palestine, Syria, and Arabia, which when dry curls itself up into a ball, and is thus blown over the surface of the ground till it comes to a damp place when it uncurls, the pods open and shed their seed.

Many seeds are provided with a wing which catches the wind and thus aids in dispersion. Such seeds occur especially on trees, such as the pine, fir, ash, maple, sycamore, hornbeam, and many exotic species. In these cases the seeds are large, but many herbs have small seeds provided with foliaceous expansions serving the same purpose. These are sometimes so thin as to be transparent; and in *Thysanocarpus elegans*, the membrane is even perforated by a series of holes. In other cases the seeds are provided with hairs which catch the wind, sometimes forming exquisite fairy parachutes. Such for instance are the dandelion, &c., but it is curious that very different parts of the plant are modified into these hairs: thus in the dandelion and valerian it is the calyx, in the bullrush the perianth, in the willow-herb the crown of the seed, in the cotton-grass the base. In the true cotton the whole seed is covered with hairs.

Thus then, although the result is the same, the mode of arriving at it is very different. He then proceeded to the cases in which the dispersion of seeds is effected by the agency of animals. In many cases the seed is surrounded by a sweet fleshy pulp which is eaten, while the true seeds being surrounded by a tough shell, remain undigested. Such fruits are generally brightly coloured such as the strawberry, peach, apple, currant, &c., the colours like those of the flowers serving to attract animals. In other cases the action of animals is involuntary. These may be divided into two classes: those in which the seeds adhere to animals by hooks, and those in which this is effected by sticky glands. Various cases of both were cited, and specimens shown, especially the South African *Harpagophyton*, a plant whose seeds are provided with terrible hooks more than an inch long. These seeds are said sometimes even to destroy lions, they roll about on the sandy plain, and if one attaches itself to the skin, the wretched animal tries to tear it off, and getting it into its mouth, perishes miserably. Sticky seeds are also thus transported.

SECTION E

GEOGRAPHY

Opening Address by Clements R. Markham, C.B., F.R.S., F.L.S., Sec. R.G.S., F.S.A., President of the Section.

I propose to open the proceedings of this Section by attempting to place in a clear light the objects and aims of geographers, and the position which their science holds relatively with reference to the other sciences, and positively as a distinct body of knowledge with defined limits.

Geography is a knowledge of the earth as it is, and of the changes which have taken place on its surface during historical times. These changes explain to us the laws according to which similar changes are now taking place around us. The subject may be considered from various points of view; but my present endeavour will be to introduce to you, through the remarks I propose to make, the papers that will come before you to-day and at our subsequent meetings. I shall try to do this by explaining the practical uses of geographical knowledge, and its importance to us in almost every occupation in which we may be engaged.

Our first work as geographers is to measure all parts of earth and sea, to ascertain the relative positions of all places upon the

surface of the globe, and to delineate the varied features of that surface. This great work has been proceeding from the first dawn of civilisation, and it will probably be centuries longer before it is completed. Geographers and explorers, surveyors and geodesists, of each generation, work their allotted time, gradually increasing the stock of human knowledge, by enabling other sciences and other branches of inquiry to make parallel advances. For they are all dependent on the accurate measurement and mapping of the earth. Locality is the one basis upon which all human knowledge must rest. Arts, sciences, administration, commerce, depend upon accurate geographical knowledge; and as that knowledge becomes more extensive and more exact, so will every other human pursuit gain increasing light and truthfulness.

We are still very far indeed from an accurate scientific geographical knowledge of even the most civilised countries, while by far the largest portion of the earth's surface is inadequately surveyed, and a smaller, though far from inconsiderable, part is unsurveyed or entirely unknown. In the division of labour, the geodesist produces the accurate large-scale maps which are necessary in thickly populated countries, the topographical surveyor furnishes less exact maps of more thinly peopled and less civilised regions, while the trained explorer forces his way into the unknown parts of the earth.

From the labours of these three classes of workers we, in this generation, and our descendants for many generations to come, must be content to derive our knowledge; but in the fulness of time the whole earth will be measured and delineated as Hallamshire is now. It is to the furthering of this great work that the geographers of each age devote their energies, and its advancement will increase in rapidity, because, as men become better instructed, there will be more geographers.

The construction of large-scale maps on rigorously accurate principles has as yet made inconsiderable progress. It is only in the countries of Europe, and India, and some of our colonies, and in the United States, that it has been commenced. But it is very far from being completed anywhere, and the people of Sheffield have had this fact brought home to them within the last year; for the Memoir on the Yorkshire Coal Field, published by the Geological Survey in 1878, was obliged to stop short with the limits of the county, an artificial and inconvenient line which leaves the southern portion of the field undescribed, entirely because the six-inch survey had not yet been extended over Nottinghamshire and Derbyshire. This circumstance strikes us in two ways. It reminds us that geographical work is far from being completed even in the most populous and civilised parts of our own country; and it also brings the fact home to us that the progress of other sciences is dependent upon the advance of geography.

Where the trigonometrical surveys have not been commenced, we have only those maps which are based on positions fixed by astronomical observations, on cross-bearings and chained distances, and which I call (to distinguish them from the results of trigonometrical surveys) the topographical maps. One of the oldest and most interesting of these maps is the famous atlas of the Chinese Empire constructed by the Jesuits between 1708 and 1718. But we are also dependent on such maps for our geographical knowledge of all Asia except India and Palestine, of the Eastern Archipelago, of all Africa and South America, and of the greater part of North America.

Accurate maps are the basis of all inquiry conducted on scientific principles. Without them a geological survey is impossible; nor can botany, zoology, or ethnology be viewed in their broader aspects, unless considerations of locality, altitude, and latitude are kept in view. Not only as the basis of scientific inquiry, but also for the comprehension of history, for operations of war, for administrative purposes, and for the illustration of statistics, the uses of accurate maps are almost infinite. M. Quetelet, in one of his well-known letters, declared that such graphic illustration often afforded immediate conviction of a point which the most subtle mind would find it difficult to perceive without such aid. Maps both generalise and allow of abstraction. They enable inquirers at once to detect and often to rectify errors, which, if undetected, would affect results and throw calculations into confusion. As an example of the use of maps for administrative purposes, the series constructed by Mr. Edward A. Prinsep, in India, is worthy of notice. They showed the agricultural tribes of a special district arranged according to occupancy of land, political and fiscal divisions, physical features and zones of fertility, productive power as influenced by rain or aided by irrigation, different kinds of soils, acres under different kinds of produce, and lines of traffic. Another most instructive series displays the State irrigation canals acting on improvable waste lands, the depth of wells, the rainfall and zones of drought, and the parts of the country already irrigated. As another noteworthy instance of the use of maps for statistical illustration, I may mention the interesting "Carte agricole de la France," by M. Delesse, which not only shows the extent of arable, meadow, and vine lands, and of woods, but the relative value of lands by shades and contour lines of equal revenue. The idea has been adopted by Mr. Ralph Richardson in his map of Mid-Lothian showing the annual rentals by colours; and of course the colours also indicate the positions of barren mountains, of fertile valleys, and of centres of population. Such maps ought to be far more extensively used than is now the case, for in no other way can economic and industrial facts be so lucidly and clearly, as well as so rapidly, impressed on an inquirer's mind.

The third division in which geographical delineation is classed is that comprised in the labour of pioneer-exploring and discovery. This branch of our subject excites the most interest, because the heroic devotion and gallantry of our travellers is a source of just pride to the nation; and because their perils and hardships, their adventures and discoveries surround them with a halo of romance. Yet these romantic associations are not confined to the pioneers of geography. Though less known, they equally belong to the more scientific geodesist. In the whole range of exploring narrative there is nothing more calculated to excite admiration, nothing more touching, than the devotion of Colonel Lambton, the first superintendent of the Great Trigonometrical Survey of India, the old man who was absorbed in his great work for half a life-time, who wasted away from exposure and hardship, but who, to the last, brightened up to renewed animation and vigour when the great theodolite was before him, and who died at his post in a wild part of Central India. This was sixty years ago, but quite recently the equally heroic death of Captain Basevi was recorded. At 17,000 feet above the sea, in a temperature below zero, and protected only by a light tent, this martyr to science was engaged in the delicate operation of swinging the seconds pendulum. One morning, when gallantly striving to rise from a bed of suffering and to recommence work, he died. Nor do these names stand alone. Assuredly, the more scientific surveyors run equal risks, and deserve equal recognition with their exploring brethren. Still the interest justly attaching to new discoveries naturally commands most popular applause, and the importance of opening up an unknown country cannot well be exaggerated.

In this glorious field there are still harvests to be reaped through the bravery and endurance of future travellers. In spite of all that has recently been done in Africa, there is a vast unknown tract to be discovered. In Asia, in New Guinea, in Sumatra and Borneo, in South America, wide regions also remain unexplored. Above all, the greatest problem of this age awaits solution in the far north, and will call forth the best scientific ability, and all the highest qualities of our naval explorers.

Every year new regions are brought within our knowledge, and we are able to welcome the adventurers home, and to add them to the list of geographical worthies. But, with regard to many explorers, there can be no doubt that much more valuable information might be obtained than is now the case. Men, with various avocations, traverse unexplored or little known countries, who, from want of previous training are unable to lay down their routes or to observe with scientific accuracy and intelligence. There are naval and military officers, missionaries, consular agents, colonial officials and planters, engineers, telegraphers, collectors, and sportsmen or persons merely travelling for pleasure, many of whom are led, by business or curiosity, to penetrate into regions of which little is known. It is most important that there should exist, in this country, the ready means of furnishing the necessary training to such explorers; and the subject has recently received serious consideration from the Council of the Royal Geographical Society.

It has been resolved that a course of instruction shall be supplied by the Society to all who are about to visit unknown or little known countries, and who desire such training. As a preliminary measure, the present arrangement is to give such instruction as will enable the pupil to fix positions by astronomical observations, and to lay down his route; but this is only a beginning, and it is to be hoped that, in due time, such a course of instruction will be provided as will enable an intelligent

traveller to observe with scientific accuracy, and to bring home really valuable results in various branches of inquiry. It is very desirable that this resolution of the Geographical Society should be widely known, and I trust that the local members of this section will co-operate so far as to bear in mind that this aid is offered by the Geographical Society, when the intention of any native of Hallamshire to visit a distant region comes to their notice. Incalculable good may be done to the cause of geography by a system which will have the effect of making every traveller a scientific and intelligent observer.

The surveying and mapping of the ocean is only second in importance to that of the land; and this work also divides itself into three sections, namely, the coasts surveyed, the coasts partially surveyed, and the unsurveyed coasts. Hydrography will not be completed until all the coasts in the world are included in the first section, which is now very far indeed from being the case. Yet this is not merely a question of science, of the study of the physical geography of the sea, interesting as this branch of our subject has become. Upon the accuracy and completeness of charts hangs the safety of thousands of lives, and the prosperity of commerce in all parts of the world. When it is remembered how much depends upon the work of marine surveys, it must be a subject of astonishment that so many hundreds of miles of coast line frequented by our shipping remain unsurveyed; and that even, in some cases, when the surveys have been executed and charts published by foreign governments, they are not accessible in an English form. In the interests of humanity and of the well-being of our trade, the efforts of geographers in urging the completion of marine surveys ought to be cordially seconded by Chambers of Commerce, and by all those whose material interests are concerned in the provision of accurate charts of all coasts visited by our shipping.

Hitherto I have invited your attention to the basis of geography, to the measurement of the surface of land and sea, and of their heights and depths; to the mapping of the world, and to the innumerable uses of maps and charts. But this only forms the skeleton of our science, which is endued with flesh and blood, with life and motion, by those who study the causes and nature of the changes that have taken place and are now taking place upon the earth; by comparative and physical geographers, by those who study and classify natural phenomena, and demonstrate their connection with each other and their places in the great scheme of nature.

Geography and geology are, from one point of view, sister sciences. The former treats of the earth as it now is and of changes which have occurred within historical times. The latter deals with the condition of the earth and the changes on its surface which went on during the cycles of ages before the dawn of history. The two sciences are quite distinct, while they aid each other. No geological survey can be undertaken without the previous completion of geographical maps, and the geologist is enabled to comprehend the condition of the earth in remote ages by studying the phenomena of physical geography. On the other hand, the geographer acquires a correct understanding of the present state of the earth's surface by considering the records of those marvellous changes which can be gathered from history and from the narratives of travellers and observers in all ages. Without their services, geography would lose half its interest.

Comparative geography (the study of the changes which have taken place on the earth's surface within historical times) is, therefore, a most important branch of our science; and it enlists the historian and the topographer in our service. It is a branch of geography which has not hitherto received the amount of attention it deserves.

The importance of the study of history and of early narratives for the elucidation of points in physical geography will appear from the consideration of a few instances. Take for example the great and fertile basin of the river Ganges in India. The Sanscrit historian finds reason for the belief that in 3000 B.C. the only habitable part of the alluvial plain of India was the water-parting or ridge between the Sutlej and the Jumna. The rest was a great estuary or arm of the sea. It has only been fit for man's occupation within the historical period, and hundreds of square miles of the delta have become habitable since the days of Lord Clive. The wonderful history of these changes can be traced by the student, who thus enables the geographer to explain the phenomena which he observes. Mr. Blanford, in his charming work on physical geography for the use of Indian schools supposes a native of the country to be standing on the bank of the river that flows by his village, watching the turbid flood swirling past. The *chur* opposite, which the river left dry when its waters fell at the close of the last rainy season, and which, till lately, was covered by a rich green crop of indigo, is now more than half cut away, and buried beneath the water. Masses, many times larger than the house he lives in, from time to time detach themselves, and are swallowed up by the deep muddy stream. If the Hindu ponders over what he sees he will perhaps be led to make inquiries, and old people will probably tell him that half a century ago the river itself was a moderate-sized *khall*, and that the old channel, seven or eight miles off, now little more than a string of pools, was at that time a great river. These facts and their causes will open to him an interesting chapter in physical geography; which is made more complete and more interesting by the ancient records of his people. But geography is an applied science. This body of facts and their causes is not a subject for mere speculative study only. It is of practical utility; for the knowledge of the way in which Nature has worked in past ages discloses her present and future operations, and enables the enlightened administrator and engineer to work in harmony with them.

Again, to pass to another part of the world. The student of history reads of the great sea fight which King Edward III. fought with the French off Sluys; how, in those days, the merchant vessels came up to the walls of that flourishing seaport by every tide; and how a century later a Portuguese fleet conveyed Isabella from Lisbon, and an English fleet brought Margaret of York from the Thames, to marry successive Dukes of Burgundy at the port of Sluys. In our time if a modern traveller drives twelve miles out of Bruges across the Dutch frontier he will find a small agricultural town surrounded by corn fields and meadows, and clumps of trees, whence the sea is not in sight from the top of the town-hall steeple. This is Sluys. A physical geographer will seek out the causes which have brought about this surprising change. They are most interesting, and most conducive to an intelligent comprehension of his science, and he will find them recorded in history. Thus the historian and the geographer work hand in hand, each aiding and furthering the researches of the other.

Once more. We turn to the great Baie du Mont Saint Michel, between Normandy and Brittany. In Roman authors we read of the vast forest called "Setiacum nemus," in the centre of which an isolated rock arose, surmounted by a temple of Jupiter, once a college of Druidesses. Now the same rock, with its glorious pile dedicated to St. Michael, is surrounded by the sea at high tides. The story of this transformation is even more striking than that of Sluys; and its adequate narration justly earned for M. Manet the gold medal of the French Geographical Society in 1828.

Once again let us turn for a moment to the Mediterranean shores of Spain, and the mountains of Murcia. Those rocky heights, whose peaks stand out against the deep blue sky, hardly support a blade of vegetation. The algarobas and olives at their bases are artifically supplied with soil. It is scarcely credible that these are the same mountains which, according to the forest book of King Alfonso el Sabio, were once clothed to their summits with pines and other forest trees; while soft clouds and mist hung over a rounded shaggy outline of wood, where now the naked rocks make a hard line against the burnished sky. But Arab and Spanish chroniclers alike record the facts, and geographical science explains the cause.

There is scarcely a district in the whole range of the civilised world where some equally interesting geographical story has not been recorded, and where the same valuable lessons may not be taught. This is comparative geography.

The peasant of Bengal sees the mould falling into his turbid river, and learns the first lesson of a course which teaches him the history of the formation of the mighty basin of the Ganges. So should we, in England, to use the words of Professor Huxley, "seek the meanings of the phenomena offered by the brook which runs through our village, or of the gravel pit whence our roads are mended." Their meaning is equally significant, equally instructive, and it is thus that we should all begin to learn geography.

M. de Brazza read a paper *On his Exploration of the Ogové River*, details of which have already been published at various times in NATURE. After leaving the basin of the Ogové and crossing the watershed he came upon the Alima, a large river flowing eastwards, which he has no doubt is a tributary of the Congo.

Captain Gerald Martin had sent home, from the seat of war, a paper *On the Afghan War—the Kurum Valley.*—Captain Martin wrote from the Peiwar Kotal, and he reported on the survey operations conducted by officers of the Indian Survey Department attached to the "Kuram Column" of the Afghanistan expeditionary force. The area comprised the whole of the Kuram Valley and the district of Khost to the south, representing an addition to our geographical knowledge of 4,500 square miles. The paper concluded with a very interesting account of the botany of the Kuram Valley and of its forest-clad slopes (which was furnished by Dr. Aitchison), and with a detailed account of the Hill tribes. The inhabitants of the Kuram Valley are agriculturists and their irrigation works gave evidence of immense labour. A paper by Captain R. Beavan was read describing the country between Kandahar and Girishk.

Lieutenant St. George C. Gore described the *Pishin Valley*, which is now to be annexed by the British Government. Its extreme length is about 48 miles, and its average width including the hill ranges on either side, from 25 to 30 miles. It is a perfectly open, nearly flat, alluvial plain, with a very barren aspect owing to the absence of trees, except fruit trees in a few gardens.

SECTION F—ECONOMIC SCIENCE AND STATISTICS

Prof. Leone Levi delivered an address upon *The Scientific Societies in Relation to the Advancement of Science in the United Kingdom.*—The importance of the subject, and the renewed effort to rear a building in the Metropolis for several scientific societies, now insufficiently accommodated, had induced him to submit the paper. In the seventeenth century there were only two scientific societies in this country; but at the present time, in an age often described as wholly given to the ignoble occupation of money-making, the calendar exhibited an amount of activity quite unknown at former periods. The membership of the three Royal Societies was then mentioned, and Prof. Levi gave many interesting particulars of societies instituted for the promotion of the physical and mathematical sciences, natural history and biology, archæology and geography, the applied sciences, and instanced a large number of miscellaneous societies. Altogether, including local scientific societies, the number of members of scientific societies in the United Kingdom is about 60,000, or deducting ten per cent. representing those belonging to several societies, about 54,000 individual members. But even that could be scarcely considered as representing men of science, and probably about 25,000 persons was the number of people who had any recognised status in the world of science, or who were actually engaged in the pursuit of science within the British isles. Some facts were then given as to the income of scientific societies.

Eliminating from the total vote the amount expended for elementary education, the proportion devoted to science and art has been considerably diminished. In 1835, the Government of the day voted 65,000*l.* for elementary education, and 70,000*l.* for science and art, or a proportion of 52 per cent. for science and art. In 1878, the vote for elementary education amounted to 3,624,000*l.*, and that for science and art to 529,000*l.*, or a proportion of 12 per cent. for science and art. Further, Government aid was principally given to physical and natural science, leaving a wide range of scientific exploration altogether unassisted. Great had been the achievements of science in modern times, and England owed to its cultivators a profound debt of gratitude. Our manufactures and industry, our productive power and means of locomotion, all depended for their development on the advance of science, and these scientific societies had a high economic value. Much more, however, remained to be accomplished, and England's hope to maintain her high position in productive industry must depend on the success which men of science might attain in fathoming the inexhaustible secrets of nature, on the increase in the number of patient yet ardent votaries of science, and still more on the diffusion of education and scientific knowledge among the great body of the people.

SCIENTIFIC SERIALS

Bulletin of the United States Geological and Geographical Survey of the Territories (vol. v. No. 1. Washington, February 28).—Notes on the Aphididæ of the United States, with descriptions of species occurring west of the Mississippi, by Chas. V. Riley and J. Monell.—The relations of the horizons of extinct vertebrata of Europe and North America, by E. D. Cope.—Observations on the faunæ of the miocene tertiaries of Oregon, by E. D. Cope.—Notes on the birds of Fort Sisseton, Dakota territory, by Chas. E. McChesney.—Palæontological papers, No. 9.—Fossils of the Jura-trias of South-eastern Idaho, by C. A. White, M.D.—Jura-trias Section of South-eastern Idaho and Western Wyoming, by A. C. Peale, M.D.—Fossil forests of the volcanic tertiary formations of the Yellowstone National Park, by W. H. Holmes.—Palæontological Papers, No. 10.—Conditions of preservation of invertebrate fossils, by C. A. White, M.D.—Supplement to the bibliography of North American invertebrate palæontology, by C. A. White, M.D., and H. Alleyne Nicholson. This supplement embraces publications which have been made during the year 1878, and also all the omissions pertaining to the first list issued as No. 10 of the Miscellaneous Publications of the U.S. Geological Survey. The year 1878 was not productive of many memoirs on North American invertebrate palæontology. Dr. White records the publications made in the United States, Prof. Nicholson those made in British North America, West Indies, and Europe.

THE *Verhandlungen der k. k. geologischen Reichsanstalt, Wien* (No. 10, 1879) contain the following papers:—On a new occurrence of celestine in the Banat Mountains, by Fr. von Hauer.—On the distribution of Silurian deposits in the Eastern Alps, by G. Stache.—On a peculiar variety of the greenstone of Dobschau, by S. Roth. The peculiarity of this rock consists in its copious tenor of calcspar, beside felspar and hornblende. Apart from these principal constituents, augite, diallage, and secondary quartz are represented in the mixture. Here and there the hornblende incloses small crystals of pyrites and of nickeline.—On *Cyclocladia major*, Lindl. and Hutt., by Karl Feistmantel.—On a collection of petrifactions from the Silurian deposits made by Herr M. Dusl at Beraun, by Prof. G. Laube.—On the recent eruption of Mount Etna, by Ad. Pereira. The author gives a somewhat scanty description of an ascent he made during the last eruption, during which he actually reached the active crater.—The last paper in the number is a valuable account of an excursion into the district between the Bosna and Drina Rivers (Bosnia), by Dr. E. Tietze.

THE *Rendiconto delle Sessioni dell' Accademia delle Scienze dell' Istituto di Bologna* (1878-79).—From this part we note the following papers:—Observations on some habits of *Vespertilio murinus*, L., and on some studies in comparative anatomy connected with this animal, by Sig. Ercolani.—Notes on an ancient Phœnician skull found in Sardinia, compared to similar skulls of the present time, by Sig. Calori.—On the decomposition of salts of a volatile base and its importance in toxicological operations, by Sig. Selmi.—Note on certain fermentations at low temperatures, by the same.—Researches on the principal phases of the annular eclipse of the sun of July 19 last, partially visible at Bologna, by Prof. Saporeti.—On the ossification of the humor vitreus of the human eye, and on some other strange modifications of the same, by Sig. PARIS

Academy of Sciences, September 1.—M. Daubrée in the chair.—M. Faye presented, in the name of the Bureau des Longitudes, the *Connaissance des Temps* for 1881, and mentioned the improvements introduced.—The following papers were read:—Mathematical theory of the oscillations of a double pendulum by Mr. Peirce; note by M. Faye.—Note on solar temperatures, by M. Janssen. The expression, *temperature of the sun*, is wanting in precision, and the methods of measurement adopted are faulty, in view of the want of homogeneity in the solar surface, and the vast envelopes which prevent the radiation reaching us in all its force. To conclude the temperature of the photosphere from its radiating power, one should know the emissive power (which is, however, unknown to us). The common methods may give truly the calorific force of solar radiation which reaches the earth's surface, but they give no exact notions of even an average temperature (which expression, indeed, is inapplicable to the sun). M. Janssen's efforts are now directed to a study of the sun in each of its distinct parts, employing analytical methods, and especially photography of the spectra of portions studied.—On the chemical constitution of alkaline amalgams, by M. Berthelot. The addition of solid mercury to amalgams containing already several equivalents of this metal liberates little or no heat, just as in the addition of solid water to saline hydrates, which already contain several equivalents of water; nearly all the heat or work having been developed in the previous combination. This gives a new relation between saline hydrates and metallic alloys.—On the projects of an American maritime canal, and of communication between Algiers and Senegal, by M. de Lesseps. He presented a volume of proceedings of the International Congress and reports relating to the former scheme. As to the latter, he thinks it would be well to commence by establishing telegraph stations at various points where water is obtainable.—On a means of diminishing the loss of *vis viva* in a divergent ajutage of large dimensions, the angle of which is too open, and which may be divided into several by conical surfaces having the same axis, by M. de Caligny.—On a process of obtaining in any ball governor the degree of isochronism desired, &c.; practical rules, by M. Leanté.—Anatomical and morphological researches on the nervous system of insects, by M. Brandt. *Inter alia*, it is untrue that all insects have a sub-œsophagean ganglion separate from the others (*Rhizotrogus*, *Stylops*, and *Hydromedra* have not). The circumvolutions of the brain are found in *all* insects, in various development, and the development differs in individuals of the same species. In general, the development of the hemispheres, but not of the whole brain, is related to instincts and habits. In some insects having two thoracic ganglions, the first is simple, the second compound; in others both are compound. The transformation of the nervous system takes place in some insects by reduction of the number of ganglions; in others by an opposite process.—On two new elements in erbine, by M. Cléve. The spectrum of the old erbine is attributed to three distinct oxides. The two new elements he designates *Thulium* (from Thule, the old name of Scandinavia) and *Holmium* (a derivative from the Latinised name of Stockholm).—Prof. Lawrence Smith remarked on the doubts of some *savants* as to the results of recent study of earths of the yttrium and cerium group.—Partial synthesis of milk-sugar and contribution to synthesis of cane-sugar, by M. Demole.—Reaction of tungstates in presence of mannite, by M. Klein.—On the determination of urea; reply to M. Esbach, by M. Méhu.—On the physiological effects of formiate of soda, by M. Arloing. It lowers the animal temperature, accelerates the respiratory movements, &c., is poisonous when the dose exceeds 1 gr. per kilog. of weight of the animal. It might be advantageously used for salicylate of soda in some cases.—On some facts relating to contraction, by MM. Brissand and Richet.—Morphological and zoological researches on the nervous system of dipterous insects, by M. Künckel.—On the plurality of nuclei in certain plant cells, by M. Treub.

COLOUR-BLINDNESS

Colour-Blindness, its Dangers, and its Detection. By B. Joy Jeffries, A.M., M.D., Ophthalmic Surgeon. (Boston, America: 1879.)

SOME months ago the subject of colour-blindness was introduced into the columns of this periodical as bearing on a question of colour nomenclature. Little was then said on the subject itself beyond what was necessary to illustrate the point in dispute, but it may now be added that the general features of this remarkable defect of vision have lately been exciting much attention, and have given rise within the last few years to a somewhat extensive literature, involving points on which there has been much difference of opinion and some energetic controversy.

It is just a century since the first public announcement was made, through Dr. Priestley, of a case of defective vision, which, by the account left on record, we can easily recognise as being of the kind subsequently found so common. About twenty years later we come on the well known and often-quoted description of his own case, given by John Dalton, which, after another lapse of thirty years, was commented on by Sir John Herschel in a very lucid and instructive manner. This celebrated case has given rise to the name "Daltonism," by which the complaint is most generally designated by Continental writers, but which has been objected to by the English, on the ground that it is no compliment to their great chemist to associate his name with an unfortunate natural defect in his optical apparatus. Many other words, chiefly derived from the Greek, have been from time to time proposed, but the simple term *colour-blindness*, adopted generally by English writers, and its equivalent, *Farbenblindheit*, used by the Germans, appear to answer every purpose, and to be unobjectionable. For, whatever may be the special characteristics of the defect (and on this point there are differences of opinion), it is admitted on all hands that an inability to appreciate the sensation conveyed by some particular colour or colours to the normal eye must be its most distinguishing feature.

In 1840 appeared an essay by Prof. Elie Wartmann, of Lausanne; but the first complete work on the subject was the "Researches on Colour-Blindness," by Dr. George Wilson, of Edinburgh, published in 1855. After this several memoirs are to be found, chiefly in transactions or journals; but the subject attracted little notice beyond mere curiosity, till a few years ago, when oculists and physiologists suddenly woke up to a conviction that it had a real importance, both theoretical and practical, and therefore deserved more careful study than it had yet received. This movement appears to have originated in a more vivid appreciation of certain dangers that were considered likely to arise from the employment, in railway and marine service, of persons who were colour-blind, and were consequently liable to mistake coloured signals. This danger had been clearly pointed out by Prof. Wilson, but it had required many years for its importance to become recognised. When, however, attention was roused, there was no lack of persons ready to undertake the investigation of the subject, and a host of works have appeared by many men of eminence proposing means of providing against the evil; and although the inquiries have been instituted at first with chiefly a practical bearing, they have naturally, in the hands of scientific men, been mixed up with a good deal of speculation of a more theoretical kind. Among the workers who have busied themselves with the subject may be mentioned Prof. Holmgren, of Upsala, in Sweden; Dr. Stilling, oculist at Cassel; Dr. Magnus and Prof. Cohn, of Breslau; Prof. Donders, of Utrecht; Prof. Ewald Hering, of Prague; Dr. Daae, of Norway; Drs. de Wecker and Landolt, of Paris; and Professors Delbœuf and Spring, of Liege. Unfortunately, although we know that some of our most eminent oculists in England have also lately had the subject under their consideration, their researches have not yet been made public, and it is, therefore, opportune that we are able to announce the appearance of a work which, although not by an Englishman, is in our language, and will, therefore, make the English reading public acquainted with what has been done.

The author is ophthalmic surgeon to several hospitals; he is otherwise much connected with ophthalmological matters, and has had large experience in regard to colour-blindness. He gives a good and full account of the general nature and statistics of the defect, and the means he considers best calculated for its detection; enlarging on the necessity for a systematic testing of the vision of servants on railways and sea-going vessels, and recommending the rigid exclusion of those who have imperfect colour-vision. He further devotes some attention to matters of theory, adopting and advocating the views most generally entertained.

It is impossible, in the short space of such a notice as the present, to give any extended analysis of the recent comprehensive investigations; it must suffice to make a few remarks on some of the more prominent points of interest; and first as to the statistics. Dr. Jeffries has some interesting chapters on this head, and states that variable statistics have been given by different observers, depending largely on the mode of testing.

In regard to males, he gives a table of the results obtained by eleven different observers, who had examined on the aggregate about 50,000 persons, chiefly pupils in schools, *employés* on railways, soldiers, or sailors. The proportion of colour-blind persons was given variously from 3 to 6 per cent., the average being about 4. Assuming, therefore, the examinees to represent fairly the general population, we may take it for granted that one out of every twenty-five men we meet is deficient of any true ideas respecting the colours of objects he sees around him.

With females, the case is very different, the defect in that sex being exceedingly rare. Out of nearly 20,000 women and girls examined, there were only registered forty cases of colour-blindness, or 0·2 per cent.; and some of these are of doubtful accuracy. This is a very singular fact, for which no sufficient explanation has ever been suggested; it has indeed been remarked that women devote much more attention than men to colours in general, but this has no bearing on the question, inasmuch as the evil is not a functional derangement, which

might be brought right by exercise, but a natural and congenital defect of organic structure, altogether incapable of cure or even amelioration by any means at present known.

There is every reason to believe the defect is hereditary, and Dr. Jeffries gives some data as to its transmission, showing the curious law (not, however, without exceptions) that it is transmitted *through* the females, although the females themselves escape it, thus skipping over every other generation. For example, if a man is colour-blind he will have no colour-blind children, neither will any of his sons' sons be colour-blind, but the defect will probably be found among the sons of his daughters.

It has been asserted by some authorities that a higher percentage of cases exists among people of the Jewish faith, and an ingenious question has been raised whether this may not indicate a descent from an early general type of imperfect vision, so giving a sort of support to the Gladstonian theory of development of the colour-sense. But as the fact is disputed, it is useless to trouble ourselves about any inference from it.

Another point of interest is the mode of testing and examining the colour-blind, and a large portion of Dr Jeffries', as of all other late works, is devoted to this matter. There are two distinct objects in view in such examinations: first, simply to discover whether the examinee is or is not colour-blind; secondly to find out the precise nature of his sensations of colour.

The first is of the more practical importance, and it is aimed, of course, chiefly at the testing of railway servants and others who have to do with colours. I hold a strong opinion that too much alarm has been created about the danger of mistaking railway signals. Normal-eyed people (who have always the greatest difficulty in comprehending what the colour-blind really see) generally believe that because under certain circumstances a red and a green object give similar impressions to a Daltonian, therefore he must, under all circumstances, confound redness and greenness. Nothing can be further from the truth, and I may give my own experience with railway signals as an example. I have had a great deal to do with railways, and although there can be no doubt about my colour-blindness, I do not recollect that I ever experienced any difficulty in distinguishing a red lamp from a green one. They are always strongly contrasted to my eye, and often, when I have passed at night through Cannon Street Station, I have amused myself by watching the changes in the imposing array of signals exhibited there. I could give a sufficient explanation of this, but it would be out of place here. I believe, so far as my knowledge at present goes, that nearly all colour-blind patients see the distinction as well as I do; and this view is corroborated by the great fact that, although we may assume that down to a late period about one out of every twenty-five engine-drivers has been colour-blind, never since railways have been in use has a single accident occurred which has been positively attributable to the mistaking of a red for a green night signal. If the notions of the alarmists were well founded, we should have had collisions every day. At the same time I do not deny the possibility of danger, under certain circumstances, and I would by no means discourage the precautions proposed in the selection of men.

It is not so easy a matter to identify positively a case of colour-blindness as might at first be supposed. Mere inaccuracy in naming colours is not sufficient, for it often happens, on the one hand, that normal-eyed people name colours incorrectly, and, on the other hand, that colour-blind people will name many colours correctly. There have been several kinds of tests adopted by different examiners, but the most important are those by Holmgren, Schilling, and Daae. The first is the one recommended by Dr. Jeffries, and it is described by him at considerable length. The test is made with a large number of samples of worsted (or what we call Berlin-wool) of a great variety of colours and shades. A certain sample, of a pale but decided tint of green, is shown to the patient, who is desired to select from the heap all the specimens which, to his eye, match it in colour. If he is normal-eyed he will select only green samples, but if he is colour-blind he will add others of other colours, such as pink, light-brown, gray, &c., which, though so different to the normal-eyed, match the green tint to his defective vision. But the wools have to be carefully selected, and are expensive. Dr. Schilling's test consists of a set of lithographed coloured diagrams; he takes two colours which, though normally strongly contrasted, he knows appear alike to the colour-blind, say scarlet and yellow-brown, and he draws letters or patterns in one of these, on a ground of the other, *i.e.*, a scarlet pattern on a brown ground, or *vice versâ*, the design being so ingeniously arranged as to avoid betraying any lines of division. A single glance at these diagrams by a colour-blind person suffices to test his vision. If he is normal-eyed the patterns are visible to him; if he is colour-blind they are invisible, the whole diagram conveying to his mind the idea of one uniform colour.

Dr. Daae's test is a little page of samples of coloured worsted, arranged in rows. Some of the rows are devoted each to one colour, arranged in different tints and shades, while other rows contain different colours in the same row. If the patient is unable to distinguish between these two classes he is colour-blind.

All these tests are very simple, and appear to be efficient so far as the mere detection of the fact is concerned, which is all that is wanted for economic purposes.

But some of the investigators go farther; they prescribe other tests with a view to find out what is the nature of the patient's vision—to get an idea of what he actually sees. The arrangements proposed for this purpose are much more elaborate. Holmgren, for example, exhibits other samples of wool, and endeavours to infer the nature of the vision by observing what colours are considered to match it. Schilling has different sets of diagrams for what he considers different classes of the complaint, while many other contrivances, some of them extremely complicated, have been designed to test the vision by shadows, by coloured glasses, by reflected images; by polarisation, by contrast, by comparisons, and by the spectroscope. These are all more or less unsatisfactory, and the information hitherto obtained by them is worth very little. The answers of the patients are seldom trustworthy, and they are almost always interpreted by the examiner to suit some preconceived theory of his own. One of the most earnest and industrious investigators, Dr. Cohn, gives a long list of answers he has

received, but he has unfortunately vitiated his whole work by relying to a large extent on the naming of colours by the patients. This is the very worst and most fallacious test of all, and Dr. Jeffries quotes, in reference to it, the following forcible remarks by Helmholtz :—

"As to the examination of the colour-blind, simply asking them to name this or that colour will naturally elicit but very little, since they are then forced to apply the system of names adapted to normal perception to their own perception, for which it is not adapted. It is not only not adapted, because it contains too many names, but in the series of spectral colours *we* designate differences of tone [hue ?] as such, which to the colour-blind are only variations of saturation or luminosity."

My own experience enables me thoroughly to corroborate this : if any one asks me to name a colour shown me, I tell him it would be as reasonable to treat me as a clairvoyant and to expect me to read the contents of a sealed envelope.

But these inquiries, as above stated, always have to do with the *theories* of colour-blindness, and a few words must be said on this point, which is one of great difficulty, and in regard to which the state of knowledge is at present exceedingly unsatisfactory. When Dalton wrote what may be considered the first good account of the defect, he, notwithstanding his great acuteness and his extraordinary powers of scientific investigation, failed to discover the important point of his case, namely, that he saw *two colours only*—yellow and blue. This was found out for him at a much later period by the penetration of Sir David Brewster and Sir John Herschel, who designated the malady by the term, *dichromic vision*, which has ever since been used. Sir David Brewster, acting on this, framed a very simple explanation of the defect, founded on his own views as to the nature of colours. He had a theory that the solar spectrum was formed from three separate spectra overlapping each other, one giving red light, one yellow, and one blue, which might therefore be considered the three primitive colours for normal eyes, as it was taken for granted all other colours might be compounded from them. All that was necessary for the explanation of colour-blindness was to assume the eye of the patient insensible to the red rays, and the phenomena followed as a matter of course. This theory was a very plausible one, and is still in favour with many persons who have practically to do with colour. But unluckily on further examination it was found wanting, inasmuch as one of the main effects in it, namely, the supposed production of green by a mixture of yellow and blue, turned out to be a delusion ; and moreover, as the theory of light became better known, the idea of overlapping spectra was abandoned, it being clear that every hue of colour had its own peculiar generating wave. Hence Brewster's elegant and simple explanation of colour-blindness fell to the ground.

Some years afterwards came out what is called the "Young-Helmholtz" theory, which assumes that the normal visual organs are capable of being impressed with three colour sensations, corresponding to red, green, and violet, and that all colour-perception is caused by the combined action of these in varying proportions. It is then assumed that in colour-blind people one of these sensations is wanting, leaving only the other two in action, and thus causing dichromic vision. The most common defect is supposed to be blindness to red, and on this hypothesis the colour-blind ought to see only violet and green. At the same time the supporters of this theory fancy they can detect some cases where the green is wanting, leaving only red and violet, and others where the violet is wanting, leaving visible only the red and the green.

This theory is in great favour, owing to the eminence of its authors and the support of many distinguished physicists ; and it is adopted implicitly by Dr. Jeffries. But objections have been raised to it on several grounds, one of the most forcible being that it does not accord with the experience of the colour-blind. If there is any one fact more unequivocally deducible from their evidence than another, it is that the less refrangible colour they perceive corresponds to yellow, and not to green. In my own case, which I believe is a typical one, my long-wave colour is most vivid and positive, and it is an absolute certainty that its maximum splendour is excited by the buttercup, or by the pigment chrome-yellow, or by the sodium line ; whereas objects that I hear called green give me no definite impressions at all ; sometimes they assume a debased, dirty, or washed-out buttercup colour ; sometimes they look black or grey ; and sometimes they even give my opposite sensation, blue. How, therefore, it can be argued that my most brilliant buttercup sensation is excited by green objects rather than by yellow ones, is to me unintelligible.

A theory has lately been started by a Belgian *savant*, that the colour-blind defect is caused by an undue sensitiveness to green, which destroys the proper effect of other colours ; to illustrate which he says that the normal eye, by looking through a certain green solution, will become colour-blind. But he carries his theory to the further length of asserting that if a colour-blind person looks through a certain red solution, he will be restored to normal vision, a conclusion which is so improbable that we may dismiss the theory from consideration, particularly as it has found no supporters.

There is, however, another hypothesis lately offered, which has a very different aspect. It was laid before the Academy of Sciences of Vienna a few years ago by Herr Ewald Hering, Professor of Physiology at Prague. Its scope is considerably wider than has to do with our present purpose, as it embraces the whole physiological theory of the perception of light, and it would be out of the question to give a complete account of it here. It is, however, of such great importance, and has been so favourably received by some of the highest authorities, that it may be worth while to devote a future article in NATURE to its description. Meantime it may be briefly stated that the author assumes, not three fundamental colour-sensations, as in the Young-Helmholtz theory, but (excluding black and white, for which he provides separately) *four*, namely, blue, yellow, red, and green.[1]

These, however, result from only two sources of sensation, each of which is capable of a double, or reversible, mode of excitement (in a manner somewhat analogous to positive and negative in electricity, or plus and minus in algebra), producing the sensation of two colours complementary to each other. Thus, one of the sources of sen-

[1] In the description of my own case, published in the *Philosophical Transactions* for 1859, I ventured to express the view that the assumption of these four colours as fundamental, was necessary in order to explain satisfactorily the phenomena of colour-blindness.

sation corresponds to blue and yellow, the blue rays exciting it in one direction and the yellow rays in the other. The other source corresponds to red and green, and is excited in like manner. It will at once be seen with what admirable simplicity this will explain colour-blindness, avoiding the violence done to the evidence by the Young-Helmholtz doctrine. Normal-eyed persons possess both sources of sensation; colour-blind persons possess only one. The usual case is when the red-green source is absent, the patient seeing only blue and yellow; but the other defect is possible, giving blindness to blue and yellow, and vision only of red and green; and Dr. Stilling, who strongly espouses the theory, states that rare examples of this have been found. If both sources of sensation are absent, the patient sees only light and shade, and this case also is said to have been practically known.

It is a pity Dr. Jeffries has omitted to mention this theory, which, if it should be substantiated by further inquiry,[1] bids fair to be a most valuable contribution to our knowledge. In the meantime the phenomena of colour-blindness, from the important bearing they have on the nature of colour-perception generally, require much further careful investigation.

WILLIAM POLE

OUR BOOK SHELF

Elementary Lessons on Sound. By Dr. W. H. Stone, Lecturer on Physics at St. Thomas's Hospital. (London: Macmillan and Co., 1879.)

SINCE the publication, some five and twenty years ago, of Helmholtz's great work on musical acoustics, the study of the nature of sound has become popular. The ordinary phenomena of hearing must interest every one; but it is to the thoughtful student of music that the subject presents its chief attractions. We cannot imagine any intelligent musician who will not be desirous to know something of the foundation of the wonderful fabric he has to deal with, and to learn how the principles of science bear on the practice of the art.

It is well, therefore, that Messrs. Macmillan have included among their School Class Books one which gives, in a very small compass, a large amount of information as to the laws and phenomena of sound. The author has not only extracted the essence of what is contained in bulky and expensive treatises, sometimes in foreign languages, but he has also given much additional information from memoirs and transactions of scientific societies out of the reach of the ordinary public.

The application of acoustics to musical instruments is a useful addition, the subject being one which the author has made specially his own. He has also stated some of the simplest facts of the connection between acoustical phenomena and the structure of music; but this is too wide a subject, and involves far too complicated considerations to be fully dealt with in an elementary work of this kind.

We notice a few trifling errors, as, for example, on page 3, the monochord can hardly be said to be "named after" Pythagoras; and Tartini's *terzo suono* was intended by him rather as a guide to correct double-stopping than "tuning." On page 11, line 7, the expression "first partial" is probably meant to be "first overtone." On page 76 a pretty contrivance, by Mr. Francis Galton, is ascribed to Capt. Douglas Galton. These things are, however, of little consequence.

[1] It may be mentioned that one of the main points in the theory has lately received unexpected and powerful support from the brilliant discoveries of Bell and Kühne in regard to the physiology of the retina.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Local Colour-Variation in Lizards

THE interest which some notes by Messrs. Wallace and Giglioli (published in NATURE) have called forth with regard to the local variation of colour in reptiles causes me to publish these few lines.

Since the year 1874 I have been carefully studying this subject, and therefore wish to remove the generally prevailing opinion that no endeavours have yet been made to explain it. I have not thought it necessary to write this before, thinking that my works touching this subject were known to naturalists, or would have become known through the mention Mr. Carpenter makes of them. Such, however, is not the case. Neither English nor Italian zoologists have taken any notice of the newer German publications concerning the local variation of colour in lizards. They content themselves with merely mentioning many new and truly interesting instances of this variation, but leave unnoticed all attempts made to obtain an explanation of the same.

The first effort to explain this appearance was made by Mr. Eimer in 1872, at the time that the beautiful black and blue lizard was discovered on the Faraglioni rocks, near Capri. Prof. Eimer tries to explain this change of colour in the *Lacerta muralis* (which is green both on the Continent and the Island of Capri) by attributing it to an adaptation to the colour of the Faraglioni rocks. However, as those rocks are not of a bluish-black, but rather a yellowish-red colour, intermixed with a little gray, and as, moreover, the lizards there have no enemies against which they require protection, and therefore no adaptation is necessary, I considered Prof. Eimer's explanation a failure, and at the same time I tried to confirm by fresh facts my hypothesis made in 1874 ("Ueber die Entstehung der Farben bei den Eidechsen," Jena, 1874). This hypothesis, which, it is true, has till now met with little approval, is as follows:—The skin of the lizard has two layers of pigment. The black pigment, which lies lowest, gets the power, under the concentrated influence of the sun, to leave its motionless state, and is made to rise by the contraction which the nerves exercise on the cells containing it, and by forcing itself more or less upwards through the elements of the pale layer of pigment, gives us the impression of different colours. That change of colour which we are able to observe in chameleons in a short space of time, under the condition of a frequent change of light, takes place with lizards only in the course of ages, embodying itself in manifold degrees of development, and provided the animal does not change the locality, remains as a distinguishing characteristic of the form. If, however, the lizard changes its locality, if it is isolated on a rock or islet which has separated itself from the mainland, and is entirely and constantly exposed to the rays of the sun, as must naturally be the case on rocks which, like the Faraglioni or the Island of Ayre, are void of all vegetation, in that case, I say, the black layer of pigment is set in motion, and by constant successive risings to the surface at last gains a definite superposition over the yellow pigment, as has been the case with the black Faraglioni and Lilfordi lizards.

This phylogenetic development of colours can be traced (as I have already mentioned in the year 1874) by the individual development of colour in the lizard, but necessarily only under the constant strong influence of the sun on young individuals. Dr. Braun, in his work on the *Lacerta lilfordi*, informs us that the young lizard of the Island of Ayre has exactly the same colour as its typical form on the larger Balearic islands, and only turns black in the course of its growth.

Though we can only observe the turning black of these lizards in the individual growth of the animal, we can obtain a returning of the full-grown animals to their original paler colours by artificial means, that is, by preventing the rays of the sun from falling on them perpendicularly. By these means I completely discoloured numbers of the Faraglioni lizards and the brown ones from the island of Ponza. The former turned bluish-green, the latter brownish-green.

Before I pass on to an enumeration of the above-named trans-

formed lizards, I shall just mention a third endeavour which has been made to explain the black colour of the lizards inhabiting small islets.

In his interesting book, "Beiträge zur Descendenz-Theorie," Leipzig, 1876, Seidlitz has tried to introduce the belief that the black colour serves as an armour or protection to the animal against the burning rays of the sun. Thereupon I sought to prove that reptiles inhabiting the desert would need such a protection more than the others, yet they are not black.

As some might perhaps draw, from what I have said, the conclusion that, according to my hypothesis the reptiles of the desert should be also black, I must remark that the scorching rays of the sun in the desert effect so strong an elevation in the temperature of the soil, that it brings forth a relaxation in the animal, and slackens the energetic movement of the pigment, consequently the extreme heat counteracts the effect which the light produces, whilst on the islets of the Mediterranean the heat is alleviated by the sea breezes and by a certain degree of dampness. As we already know, all our European species of lizards carefully avoid the desert.

The dark-coloured lizards at present known, which inhabit small islands, are the following ones:—

1. *Lacerta muralis, var. archipelagica*, De Bedriaga: "Die Faraglioni-Eidechse." (Heidelberg, 1876; pp. 19.) *L. muralis, var.* B. Erhard: "Fauna der Cykladen," (Leipzig, 1858; pp. 80.) *L. muralis, var. C.*, Schreiber: "Herpetologia europæa." (Braunschweig, 1875; pp. 408.) *L. muralis, var. archipelagica*, v. Bedriaga: "Herpetologische Studien," im *Archiv für Naturgeschichte*, 1878.

Back and extremities black, covered with rows of green spots. Belly and tail black. Inhabits the Cyclades.

2. *Lac. muralis var. melisellensis*, Braun: *Lacerta lilfordi* and *L. muralis*; "Arbeiten aus dem zoolog. zootom. Institut in Würzburg, 1877."

Back brown, ornamented with six light longitudinal stripes. Belly dark blue, chin rather lighter. Length 130 mm. Inhabits the islet Melisello near the island of Lissa, in the Adriatic Sea.

3. *L. muralis, var. filflaensis*, De Bedriaga: "Die Faraglioni Eidechse." (Heidelberg, 1876.) Braun, *l.c.* v. Bedriaga: "Herpetologische Studien," in *Archiv f. Naturg.*, 1879. Günther: "Description of a new European Species of Zootoca," *Annals and Magazine of Natural History*, 1874.

Back black covered with small green specks, the under parts are deep blue. Length 212 mm. Inhabits Filfla, near Malta.

4. *L. muralis, var. faraglionicnsis*, De Bedriaga: "Ueber die Entstehung der Farben bei den Eidechsen." (Jena, 1874.) *L. muralis var. cœrulæa*, Eimer: "Zoologische Studien auf Capri." (Leipzig, 1874.) Braun, *l.c.*

Back black, the sides blue spotted with black; the belly a brilliant blue. Length 220 mm. Inhabits the Faraglioni Rock, near Capri.

5. *L. muralis, var. Latastei*, De Bedriaga: "Herpetologische Studien," in *Archiv f. Naturg.*, 1879, pp. 264.

Back and sides brown, or dark brown covered with black spots, sometimes with bluish green spots on the sides. Above the root of the forelegs a bluish spot. Length 205 mm. Inhabits Ponza near Gaeta.

6. *L. muralis, var. Lilfordi*, Günther: "Description of a New European Species of Zootoca," *l.c.* Braun, *l.c.*

Upper parts of a deep glossy black, lower parts of a beautiful sapphire blue. Length 175 mm. Inhabits the Island of Ayre, near Minorca.

7. *L. muralis, var. Gigliolii*, De Bedriaga: "Herpetologische Studien," 1879, *l.c.*

Forepart of the back covered with alternately green and blue stripes. The hind part of the back is dark blue. The sides are light brown with green and blue spots. The belly brick-red with (sometimes without) small blue stripes. Colouring varies. Length 175 mm. Inhabits Isla del Dragoneras near Majorca.

8. *L. muralis, var. Rasquineti*, De Bedriaga: "Herpetologische Studien," 1878, *l.c.*

Back olive brown with a black pattern. Blue eye-spots ornament the sides. Belly brick-red. The first longitudinal rows of the ventral scales are blue. Length 185 mm. Inhabits the islet La Deva near Arnao (Spain). J. VON BEDRIAGA

Heidelberg, August 28

Insect Swarms

THIS year being remarkable for "insect swarms," it is important that all possible information about them should be gained, so as to satisfactorily account for these phenomena. As to *Vanessa cardui*, which has been abundant throughout the spring and summer, it is possible that some of those specimens which occurred in the spring were the result of a migration from the Continent, but there is no doubt that the specimens which are now seen are nearly, *if not all*, bred in this country from ova deposited by the spring specimens, quite sufficient time having elapsed for the metamorphosis. With regard to *Plusia gamma*, I am of opinion that all the specimens seen, and they have been in profusion here from about August 10 till the present time, have been bred *in this country*. My reason for so believing is that the larvæ were most abundant in the spring, doing damage in gardens to a great extent. Some of these larvæ I fed up, the perfect insects emerging at the time *P. gamma* first appeared in abundance. My experience of the swarms of *P. gamma* is that they moved in no particular direction, merely passing in numbers from flower to flower, flowers being scarce this year, any apparent migration being simply a search for more flowers. Instead of putting the cause of these swarms down to "migration," endeavours should be made to discover the causes of the extraordinary periodical fecundity. It is quite probable, too, that next year, *P. gamma* and *V. cardui* will be scarce, as is frequently the case with *Colias edusa* and *hyale* after a year of abundance. J. H. A. JENNER

Lewes, September 13

Earthquakes

I HAVE observed, in several recent numbers of NATURE, various notices of earthquakes, so frequent as to suggest the idea to me (perhaps incorrect) that for several months past they have been more numerous than usual. Since my arrival in West Java I have experienced several severe shocks. On March 28, between 7 and 8 P.M., I was startled by a peculiar shivering as I sat in my chair. At first I imagined I was seized with a terrible feverless ague, but I was soon undeceived by the increased bumping and the clashing of my bottles, &c., and the vehement beseeching of *Tuhan* Allah, and the loud exclamations of the natives of, "We are here!" "We are all here!" I learned in a few days that several villages lying at the base of the peccant volcano, Gedè, had suffered; in particular the town of Ijandjoer, in which numerous houses were destroyed, many bridges broken down, the telegraph apparatus entirely thrown out of gear, and six or seven persons killed. The ground also opened and emitted volumes of smoke, while the Gedè itself burst out with extra vigour, throwing out, in addition to the usual white steamy vapour, large quantities of smoke and ashes, fortunately to no great distance. Throughout the 28th and 29th there was a succession of shocks. On June 3 I experienced a second earthquake, undulatory but not very severe; and again on the 5th, undulatory, of considerable duration, and severe enough to thoroughly shake the whole house and throw down unfixed objects. These have done no damage to life, as far as I have heard, and, beyond some houses being cracked in Batavia, little to property. Since the beginning of March there have been numerous shocks, but none so violent as those of March 28 and June 5. Immediately preceding the shock of June 5 there was a sudden and heavy fall of rain, the drops being very large. The direction of the wave was from east to west. HENRY O. FORBES

Kosala, Bantam, July

Leaping Power of Mantis[1]

I CAN state from my own observations of several different species, both in Ceylon, South Africa, and Fiji, that the power is possessed by many, chiefly in the larval stage, and that the distances they can spring from branch to branch are very considerable for the size of the insect. E. L. LAYARD

British Consulate, Noumea

OUR ASTRONOMICAL COLUMN

THE OUTER SATELLITE OF MARS.—The following positions of *Deimos*, the exterior satellite of Mars, are deduced from the data published in Prof. Asaph Hall's memoir, in which he determines the elements of the satellite-orbits:—

[1] NATURE, vol. xx. p. 595.

At Greenwich Midnight

	Pos.	Dist.		Pos.	Dist.
	°	″		°	″
Oct. 10	241·3	50·1	Oct. 21	44·0	46·8
11	28·4	23·6	22	60·8	55·7
12	55·1	61·7	23	200·6	22·4
13	98·7	15·5	24	234·0	65·7
14	229·3	56·8	25	272·4	20·6
15	245·9	42·0	26	47·1	58·0
16	39·0	36·7	27	64·9	48·6
17	57·6	60·4	28	213·4	35·0
18	161·8	12·5	29	236·6	64·7
19	231·7	63·0	30	317·7	14·4
20	254·1	31·6	31	49·7	64·2

The apparent diameter of Mars, assuming the diameter at the mean distance 9″·415, will be 17″·8 on October 10 and 19″·5 on October 31. The value adopted depends chiefly upon the double-image measures, and is smaller than that introduced in Leverrier's Tables of Mars, which was derived from observations with meridian instruments. The period of revolution of *Deimos* is 30h. 17m. 54s., and the mean distance from the centre of Mars 14,500 miles, so that the average orbital velocity is 50 miles per minute. The excentricity appearing to be very small, Prof. Hall assumes a circular orbit for prediction in 1879.

THE FIRST COMET OF 1699.—This comet was observed at Paris by Cassini and Maraldi from February 20 to March 2, and at Pekin by the Jesuit missionary, De Fontenay, from February 17 to February 26. The single orbit which figures in our catalogues was calculated by Lacaille; the following elements by Mr. Hind depending upon the observations of February 19, 24, and March 2, are very similar to Lacaille's, the only noticeable difference being an increase of rather more than 1° in the inclination:—

Perihelion passage, 1699, January 13·3998 G.M.T.

	° ′
Longitude of perihelion	212 8·8
,, ,, ascending node	321 41·5
Inclination	70 36·6
Log. perihelion distance	9·87426

Motion—retrograde.

The re-examination to a certain extent of the cometary orbits resting upon a single calculation appears by no means a futile work, as was shown by the circumstance pointed out in this column some time since, that Halley had inadvertently given the longitude of the *descending* node of the comet of 1698, in his "Synopsis of Cometary Astronomy," in place of that of the *ascending* node, and the mistake has been continued in all our catalogues.

NOTES

THE latest conflagration at Irkutsk has destroyed all the libraries of the town—the Public Library, the private one of M. Vaghine (which contained the unpublished MSS. of Gedenstrom), and that of the Siberian branch of the Russian Geographical Society, which latter contained a great variety of works about Siberia, some of them being very rare, a great number of works and MSS. on Buddhism, numerous collections of publications of foreign scientific societies (European, Asiatic, and American) who exchanged their publications with the Siberian branch, and a large assortment of works on physical sciences and natural history. The destruction of this library will be a very great loss to science altogether, if a new one be not immediately created. It would be difficult for a man of science inhabiting a great city or even the smallest town in Western Europe to understand the important services which this library—the only one in Central Asia—has rendered in the development of scientific knowledge and in giving a scientific character to the geographical exploration of Siberia. Many scientific men when staying in Irkutsk have largely made use of the library (we may name among them the well-known president of the Berlin Geographical Society, Prof. Bastian, and quote his interesting notice on Irkutsk), and the writer of these lines can testify, from his own experience, how immense were the services rendered by this library to him and to his young friends when they began their studies for scientific geographical explorations of Siberia at Irkutsk, *i.e.*, at a distance of some thousand miles from all intellectual centres. We think that all those who have the further development of scientific exploration at heart, should do their utmost to assist in creating a new and good library in that centre for the exploration of Siberia.

ON August 20 last, the centenary of the birth of Berzelius was celebrated in a fitting manner at Stockholm. All the principal newspapers commented on the event in leading articles, and reminded their readers in enthusiastic terms that through Linnæus and Berzelius Sweden obtained citizen-rights in the world of science. At Väfversunda in the province of Småland, the birth-place of Berzelius, a monument to the great chemist was unveiled on the same day, in the presence of a large concourse of country people.

THE steamship *Faraday*, which has successfully laid the new transatlantic electric cable from Scilly to Newfoundland, returns to Woolwich to take on board the shore end and the cable to be laid from Newfoundland to America. The Siemens electric works at Charlton are just now busy completing the preparation of these parts, which will be ready by the end of this month, when the *Faraday* will be moored in the Thames to receive them.

THE steamer *Dacia* left Greenwich a few days ago in order to lay the second electric cable which is to connect Marseilles and Algiers. When this communication has been established the tariff of telegraphic messages between France and Algeria will be diminished by half, being reduced to 1*d*. a word instead of 2*d*. as now. It is supposed that the augmentation of traffic with the colony will result in an increased income to the Government.

ON September 1 snow fell in the village of Neustadt (Holstein).

A TERRIBLE whirlwind is reported from the village of Hopsten, near Münster (Westphalia). It occurred on August 26, at seven P.M. The largest oaks were uprooted and broken down; many houses were partially destroyed, and *débris* of all kinds marked the path of the atmospheric disturbance, which proceeded in an easterly direction. Strange to say, the most complete calm reigned everywhere around at the time.

PHYLLOXERA has now made its deplorable entry into Italian vineyards. The destructive insect has appeared in the province of Como. The local authorities are making every effort to combat the plague.

IT was proved some time ago by M. de Heen that, for metals belonging to the same natural group, the product of the coefficient of expansion by the absolute temperature of fusion is a constant quantity. In another memoir just presented to the Belgian Academy, M. de Heen inquires how the coefficient of expansion of water varies with the nature and quantity of substances dissolved in it. He proves that there is also a remarkable relation between the coefficient of expansion of organic liquids belonging to the same homologous series and their boiling point; the product of the one by the other is a constant quantity. In connection with this, M. Spring points out that M. Pictet, guided simply by ideas introduced into science by thermodynamics, has come to the same conclusions as M. de Heen. M. Pictet shows (1) that temperature is represented by the length of calorific oscillations of the molecules of a substance; (2) that the temperatures of fusion of solids correspond to equal lengths of oscillations; and (3) that consequently, the product of the lengths of oscillation by the temperatures of

fusion must be a constant number for all solids. As the lengths of oscillation of the molecules of a body are measured by the coefficient of expansion, we see that the result is the same as that reached some time since by M. de Heen, and which is now extended to liquids.

In a series of experiments recently described to the Vienna Academy, Prof. von Waltenhofen has sought to deduce from a direct measurement of the work done in induction of an electric current in a closed circuit of given resistance, the mechanical equivalent of heat. For induction, a magneto-electric machine was used, whose electromotive force was ascertained to be proportional to the number of revolutions. A dynamometric handle of the newest construction was attached, and it was furnished with an arrangement for receiving the work-diagrams. The induced currents were measured by means of a tangent galvanometer. The results were found to be in satisfactory agreement with Joule's equivalent.

An interesting communication relating to the photography of spectra has recently been made to the Berlin Academy of Sciences by Herr H. W. Vogel. It is not very difficult to photograph the spectra of incandescent gases if the source of light is an induction spark which is produced by a current with an inserted Leyden jar. The photography of the much fainter spectra obtained by the simple induction-spark presents far more considerable difficulties, and these are the very ones which Herr Vogel has now completely mastered by the employment of so-called gelatine-dry-plates. These plates are remarkable for their extreme sensitiveness, which Herr Vogel has estimated to be at least fifteen times that of the ordinary wet plates. They keep good for years, it seems, and are already obtainable in the trade. By using them Herr Vogel succeeded in fixing the spectra of the little oxygen tubes prepared and studied by Herr Paalzow, thus rendering lines visible in the more refrangible part of the spectrum which cannot be observed by direct vision. The two gentlemen are now engaged in studying these spectra more minutely in company, and will doubtless soon publish the results of their researches.

A violent shock of earthquake, lasting forty seconds, is reported from the island of St. Thomas (West Indies). It occurred on July 30 at 11.35 A.M.

The *Temps* publishes a letter from M. Francis Laur, a mining engineer, complaining that the French Parliamentary Commission appointed for preventing the effects of fire-damp, has given no sign of life, although a credit of 50,000 francs was assigned to it, and more than fifty inventors have sent in instruments or methods for examination.

M. Ferry, Minister of Public Instruction, has published an official circular for the better organisation of the bursaries granted after examination to students taking their degrees in the several French universities. These bursaries are of quite recent foundation and present a strong similarity to the sizarships or scholarships in the English universities.

Amongst European countries there are two where science has been dreadfully neglected up to the present time. For one of these two, viz., Turkey, we are afraid there is not much hope of reformation, at least in its present condition. It is satisfactory, however, that the other one, viz., Spain, seems at last to be awaking from its lethargy with regard to science. Some time ago we had occasion to refer to a commendable *Cronica cientifica*, published annually in two volumes, by Dr. Emilio Huelin, of Madrid. Another publication which appears monthly, the *Revista contemporanea*, of which Dr. Francisco de Asis Pacheco is the editor, has just come under our notice. The last number of this serial contains an excellent article on the sciences in 1879, by Ricardo Becerro y Bengoa, giving a most elaborate account of the work done recently in all branches of science. The publishers are Señores Perojo Hermanos, of Madrid, who also publish *La Naturaleza*, an illustrated science review, in two volumes annually.

The project of building a canal from Amsterdam to the Rhine (in continuation of the new canal between that city and the German Ocean) has lately been again brought before the Dutch Government. Our readers are aware that the project is not new, and it is easy to see the great advantages its execution would bring to the commerce of Holland generally and of Amsterdam in particular.

At a recent meeting of the United States Anthropological Society, Mr. F. H. Cushing, who has made an original and experimental study of aboriginal processes in the manufacture of pottery, stone axes, and flint arrow-heads, using only the tools which were within the reach of the aboriginal manufacturers, gave an interesting description of the manner in which flint implements, especially arrow- and spear-heads, were made by the prehistoric inhabitants of this country and Europe, previous to the discovery or introduction of iron. It is the popular impression that flint arrow-heads were all chipped into shape by striking off fragments with a rude stone hammer, and this was the method first tried by Mr. Cushing. He found, however, that it was impossible to imitate in this way any of the finer and more delicate specimens of Indian arrows, and that three out of four even of the coarser forms were broken in the process of manufacture. It was evident, therefore, that the Indians had other and more delicate processes. After many unsuccessful experiments, he accidentally discovered that small fragments could be broken off from a piece of flint with much greater certainty and precision, by pressure with a pointed rod of bone or horn, than by blows with a hammer-stone. The sharp edge of the flint would cut slightly into the bone, and when the latter was twisted suddenly upward a flake would fly off from the point where the pressure was applied in a direction which could be foreseen and controlled. To this process Mr. Cushing gives the name of flaking, to distinguish it from chipping produced by percussion. And its discovery, he considers, removes most of the difficulties which previous experimenters had met with in trying to work flint without the use of iron. Spear- and arrow-heads could in this way be flaked even into the most delicate and apparently fragile shapes with a certainty attainable in no other way, and with a greatly-lessened probability of breakage. Mr. Cushing then described, with the aid of blackboard illustrations, all the steps in the manufacture of an arrow, beginning with the striking off of a suitable flake from the mass of material selected, trimming it roughly with a pebble into a leaf-shape with a bevelled edge, scaling off surface flakes by repeated blows with a hammer-stone upon this edge at right angles to its plane, and finally finishing, pointing, and notching the arrow-head with the bone flaking-instrument previously referred to.

The Russian Foreign Ministry has just published a very good Russian and Chinese dictionary, by the first translator of the Russian mission at Pekin, M. P. S. Popoff. The work is printed by a new kind of autography devised by M. Alisoff.

M. Ferry has published an order for the appointment of librarians in the establishments of the University. No one is to be appointed except after two years' trial and passing successfully a professional examination. This is to consist of a French dissertation on a given subject of bibliography, and the classification of fifteen works treating of different matters, and belonging to several periods of the history of the art of printing.

The Musée Scolaire, which had been removed by the Minister of Public Instruction to one of the halls of the Palais Bourbon, is to resume its former situation. The hall in which it had been located is wanted by the questors for the installation of the

Chamber of Deputies which, as is known, is to be transferred to Paris in November next, there to hold its sessions, so long as the Parisians do not oppose it by a revolution.

AT the Stuttgart meeting of the International Geodetic Association in 1878, M. Faye suggested a method of avoiding the flexure of a pendulum-support, viz., that two similar pendulums should be oscillated on the same support with equal amplitudes and opposite phases. The idea was thrown out on the spur of the moment, and was not received with very warm approval. By a mathematical discussion of the method in a paper to the U.S. National Academy (*Silli. Journ.*, August), Mr. Peirce endeavours to prove that the suggestion is as sound as it is brilliant, and offers some peculiar advantages over the existing method of swinging pendulums.

AT the International Alpine Congress at Geneva Prof. A. Favre pointed out the necessity of making measurements of glaciers. The retrocession of glaciers has been general during the last twenty-five years. Prof. Favre is of opinion that this retrocession period will come to an end after some time, and will be succeeded by a period of advance. The German and Austrian Alpine Club, at its last general meeting at Saalfelden, resolved to make the measurements in question on all the glaciers of the Austrian Alps.

THE third volume of Dr. Karl Russ's work on foreign domestic birds, containing the natural history and cultivation of parrots, has just been published by C. Rümpler, of Hanover.

A NEW oil plant (*Lallemantia iberica*) has been acclimatised on the fields of the Agronomical School at Cherson (South Russia). It belongs to the *Labiatæ* family, and is very similar to *Dracocephalum*. The herb attains a height of 1½ to 2½ feet and bears some 2,500 seed-grains, which give a most pure oil, applicable even for culinary purposes. The seeds of this originally Persian plant were first sent to Cherson by Prof. Haberlandt, of Vienna.

WE learn that M. Europeus still continues his most interesting researches into the prehistoric Finnish population of North-Western Russia. During last summer he explored the *koorganes* (mounds) of the province of Olonets, and on the banks of the Oyak river he discovered many bronze implements similar to those brought in by Ujfalvi from the banks of the Irtysh in Siberia. The remains of the Korels in the district of Olonets throw a new light on the geographical distribution of this people. M. Europeus has arrived at the conclusion that during the first centuries of the Christian era the whole of North-Eastern Europe and the north of the Scandinavian peninsula were peopled by tribes of Finnish-Hungarian and Finnish-Ugrian origin, who formed an extensive and strong state. Only the shores of Lake Onega had a purely Finnish population. All skulls in the *koorganes* of the region formerly occupied by Finns, are of the brachycephalic form.

COUNT T. SALVADORI'S great work on Papuan ornithology, "Ornitologia della Papuasia e delle Moluche," is in a forward state, and it is hoped that the first part (containing the Accipitres, Psittaci, and Picariæ) will be ready about the end of the year. The second part will be devoted to the Passeres, and the third to the remaining orders. The total number of species contained in the work will be about 900, the area embraced being the whole of the Austro-Malayan sub-region, with the exception of Celebes and the Timor group of islands.

A RAILWAY is now being built between Tiflis and Baku, and is expected to be completed in about four years.

WE have received the fourth volume of the *Bulletin* of the Société Ouralienne, *i.e.*, the Natural History Society of Ekaternburg, Russia. The volume contains some interesting data on the flora of the Ural Mountains, by M. G. O. Clerc; also some notes on rain-gauges and on the quantity of rain and snow which falls at Dolmatoff (average computed from observations extending over fourteen years), by the same. Another valuable contribution is by M. N. P. Boulytcheff, and treats of the flora and the fauna of the Irbit District. All these papers are given in the Russian original and in a French translation. An original German paper is by Dr. J. Hann, on the daily course of magnetic declination in Russia, but only the Russian translation is printed.

THE Congress of German Horticulturists which took place at Cassel this year will meet at Bremen next year.

AT South Arcot (Presidency of Madras) experiments have been recently made with the fibres of aloes, which grow there in abundance, with a view of preparing paper from this material. A product was obtained which considerably surpassed the ordinary Indian paper in quality, and it is now intended to make the experiments on a larger scale in this country.

THE St. Gothard tunnel, which will measure 14,920 metres when completed, has now reached a length of 13,229 metres. It is hoped that by the beginning of December next the gigantic work will be finished.

THE additions to the Zoological Society's Gardens during the past week include a Guinea Baboon (*Cynocephalus sphinx*) from West Africa, presented by Mr. F. Naylor; a White-fronted Capuchin (*Cebus albifrons*) from South America, presented by Major H. L. Gleig; a Black-faced Spider Monkey (*Ateles ater*), two Black Tortoises (*Testudo carbonaria*) from South America, two Martinican Doves (*Zenaida martinicana*) from the West Indies, presented by Capt. Henry King; a Plantain Squirrel (*Sciurus plantani*) from Java, presented by Miss Lizzie Casey; an Indian Jackal (*Canis aureus*) from India, presented by Mr. Thos. Thursfield, M.R.C.V.S.; a Demeraran Cock of the Rock (*Rupicola crocea*) from Demerara, presented by Mr. R. S. Fraser; a King Parrakeet (*Aprosmictus scapulatus*) from New South Wales, presented by Mr. Geo. Wood; a Red and Blue Macaw (*Ara macao*), a Red and Yellow Macaw (*Ara chloroptera*) from South America, deposited; an African Brush-tailed Porcupine (*Atherura africana*) from West Africa, a Vulpine Squirrel (*Sciurus vulpina*, var. *capistrata*) from North America, purchased.

THE BRITISH ASSOCIATION

REPORTS

Report of the Committee for exploring Caves in Borneo. Drawn up by Dr. J. Evans, F.R.S.—The Committee report that with the grant of 50*l.* from the Association, a similar grant from the Royal Society, and a farther sum of about 200*l.* from private sources, they have been able to prosecute an examination of various caves in Borneo, under the superintendence of Mr. A. S. Everett, who has devoted himself to the task for a period of nearly nine months.

The final report upon his work has not yet been received, but it appears from his letters and from the specimens which have been transmitted to this country, that nothing of special interest either from an anthropological or a geological point of view has resulted from his explorations. The animal remains discovered have all been of recent species; the human bones are probably of no great antiquity, and none of the few objects of human manufacture which have been found can be regarded as of palæolithic age.

Pending the arrival of Mr. Everett's final report it appears needless to enter into details; but it may be mentioned that upwards of twenty caves appear to have been explored, in a more or less complete manner, and the principal objects found, after examination by some of the members of the Committee, have been forwarded to the British Museum. Although the examination of these caves has not, as was hoped, thrown any light upon the early history of man in that part of the world, it is still satisfactory that the examination should have been made

and the character of the cave-deposits ascertained by so competent an observer as Mr. Everett. The evidence obtained, though negative, is not without value, and those who are specially interested in cave-explorations, and who have so liberally assisted in the present instance, cannot be reproached with not having availed themselves of the opportunity afforded by Mr. Everett's presence, of obtaining farther information as to the contents of the Borneo Caves.

It may be added that though for the most part the objects secured were unimportant, there were among the cave-deposits a number of shells of land and freshwater mollusca, which have been examined by Col. Godwin-Austen, and have proved to belong to at least 25 genera and 40 species, some of which are apparently new. Mr. Everett has been requested to devote some attention to collecting a larger series of these shells, but owing to the difficulties of postal communication it is possible that the request may arrive too late.

The Committee propose to communicate Mr. Everett's final report, together with any observations which seem called for on the specimens which are still to arrive, to the Royal Society.

Underground Waters.—The fifth report was presented of the Committee appointed in 1874 to inquire into the circulation of underground waters, and the extent to which they may be made available for the water supply of towns and districts. The Committee state that, as the objects of the inquiry become more widely known, there is increasing inclination shown by engineers and contractors to impart information, which accrues from day to day, and that they consider it desirable to continue their labours until it becomes the duty of some Government department to undertake the charge. They desire to extend their inquiry beyond the Permian, Triassic, and Jurassic rocks to all permeable formations yielding supplies of potable waters. A large amount of valuable information has been collected in the Midlands and in other districts, of works in progress which will be reported on next year. The attention of the Reporter of the Committee (Mr. De Rance) has been specially directed to ascertaining the areas of pervious rocks, in each of the river basins of England and Wales, and of the areas of impermeable rocks overlying permeable formations, and forming "supra-pervious" areas, together occupying an area of more than 25,000 square miles, and capable of yielding an amount of water far in excess of the quantity required for manufacturing and potable purposes. The impermeable nature of the Severn river-basin is alluded to, and the consequent danger of abstracting a large volume of its waters for Liverpool water supply commented on.

Report of the Anthropometric Committee.—This Committee had been appointed for the purpose of continuing the collection of observations on the systematic examination of heights, weights, &c., of human beings in the British Empire and the publication of photographs of typical races of the empire. Considerable progress had been made during the past year, and returns, giving the birth-place, origin and sex, age, height and weight, colour of hair and eyes, girth of chest, strength of arm and eyesight, of pupils at Westminster and other schools, London policemen and letter sorters, workmen, rifle volunteers, soldiers and criminals, had been obtained. By this means the Committee were put in possession of nearly 12,000 original observations on the main question of weight and height in relation to age, in addition to 50,000 already collected. The Committee submitted a series of tables made up from the information contained in the returns. From these it was shown that the London letter sorters were the lowest in height, the average heights between the ages of 20 and 35 being 64 to 67·1 inches. The letter sorters were also at the bottom of the weight table, their average weights in lbs. being 122·5 to 139·9. The metropolitan police were at the head of both lists; height 69·2 to 71·5 in., and weight 162·5 to 182·7 lbs. Other tables were given, showing that the average height and weight varies with the social position and occupation of the people, and that to obtain the typical proportions of the British race it would be necessary to measure a proportionate number of individuals of each class. Taking the census of 1871, they would find that a model community would consist of 14·82 per cent. of the non-labouring class, 47·46 per cent. of the labouring class, and 37·72 per cent. of the artisan and operative classes. The nearest approach to such a representative population in a limited space would be found in some of the larger county towns, such as York, Derby, or Exeter. The tables demonstrated that the full stature is attained in the professional class at 21 years, and in the artisan class between 25 and 30 years. American statistics showed that a slight increase in height takes place up to the 35th year. The growth in weight does not cease with that of the stature, but continues slowly in both classes up to about the 30th year. The report concluded by referring to similar investigations which are being made in other countries, and the coincidence of the several inquiries led to the hope that information of great value might in due course be elicited.

SECTION A—Mathematical and Physical

On Secular Changes in the Specific Inductive Capacity of Glass, by J. E. H. Gordon, B.A.—At Christmas, 1877, I made some determinations of the specific inductive capacity of optical glass by a method which has already been fully described both before this section and elsewhere.[1]

At the end of July, 1879, I commenced a repetition of the experiments, using the same slabs of glass, and was surprised to find a large increase in the specific inductive capacity in every case. In some cases the increase was as much as 20 per cent. The following is a table of the results:—

Specific Inductive Capacity of Optical Glass

	Christmas, 1877	July and August, 1879
Double extra dense flint	3·164	3·838
Extra dense flint	3·053	3·621
Light flint	3·013	3·443
Hard crown	3·108	3·310

The arrangement of the apparatus, including the coil and rapid break, was precisely the same as in my earlier experiments. The electromotive force was as nearly as possible the same, and experiment has shown that moderate variations in it do not affect the results.

The differences observed might have been caused by any one of three things:—

1. By error in the 1879 experiments.
2. By error in the 1877 experiments.
3. By a change in the specific inductive capacity of the glass between Christmas 1877 and July 1879.

[The author, after showing reason for the rejection of (1) and (2) is led to the conclusion that in the course of a year and a half an actual change has taken place in the glasses, which is shown by a considerable real increase in their specific inductive capacities.] To complete our knowledge of this new phenomenon we require a series of monthly observations, extended over perhaps a period of several years. I shall hope to be able to give the results of another year's experiments at the next meeting of the Association.

These experiments have some importance as regards Prof. Clerk-Maxwell's electro-magnetic theory of light. In a recent lecture[2] I ventured to suggest "that it is quite possible that the relation between electric induction and light exists—namely, that they are disturbances of the same ether, but that there is some unknown disturbing cause affecting the electric induction."

Possibly a clue to the nature of this disturbing cause may be found in the fact, that the specific inductive capacities are affected by some of the changes which chemists tell us are constantly going on in glasses, but that these changes do not affect the refractive indices.

SECTION B—Chemical Science

Mr. W. Chandler Roberts, F.R.S., Chemist of the Mint, read a paper *On some Experiments with the Induction Balance.*—He stated that the instrument, which we owe to Prof. Hughes, the discoverer of the microphone, appeared to be one of no ordinary importance, and although the experiments about to be described were far from complete, they possessed sufficient interest to warrant their being submitted to the Section. He then described and exhibited Prof. Hughes's instrument, showing the extreme delicacy by which changes in the induced current were indicated by the microphone and telephone.

The relative values of different metals, as indicated by the induction balance, do not accord with the values usually accepted as representing the relative conductivities of the respective metals, and this being the case, Mr. Roberts had ascertained what rela-

[1] *Report* Brit. Assoc., 1878; *Proc.* Roy. Soc., 191. 1878; *Phil. Trans.*, 1879; "Four Lectures on Electric Induction," delivered at the Royal Institution (Sampson Low and Co., 1879.)
[2] Royal Institution, February 6, 1879.

tion the indications given by alloys, when under the influence of the induced current, bear to their electric conductivities.

The experiments on a comprehensive series of alloys proved that, in the case of alloys of certain metals, the induced-current curves closely resembled those representing electric conductivity, but that in certain other cases the induced current revealed differences that had hitherto escaped observation. As an example, Mr. Roberts alluded to the curve of the copper-tin alloys, in which there is a sudden break between the points representing two alloys, which only vary by a single equivalent, or by 6·4 per cent. of copper. These two alloys are widely different in colour, fracture, density, and structure, and the induction-balance at once afforded evidence of a marked difference not shown in Matthiessen's curve of electric conductivity.

It is known that certain metals, when alloyed, undergo a molecular change, and that an allotropic condition may in some cases be induced by alloying a metal with a small quantity of another, facts which well deserve minute examination as bearing on the non-elementary character of certain metals, which is now receiving so much attention.

Mr. Roberts then referred to the question of applying the induction-balance to the assay of metals. In the case of gold-silver alloys the instrument will show the presence of less than two grains of gold in the pound of silver. On the other hand, the silver-copper alloys used for coinage are situated at the flat portion of the curve, so that it is impossible to detect even considerable differences in their composition, and these alloys which are very peculiar to their nature, appear to be greatly affected by annealing. More hopeful results were obtained with the gold-copper alloys, and Mr. Roberts demonstrated a difference of 1 per cent. in the standard of two gold disks, which, though far short of the existing method of assay in delicacy, appeared to afford grounds for the belief that very accurate results will ultimately be obtained.

Notes on Petroleum Spirit or Benzoline, by A. H. Allen.—The application of the commercial names "benzoline" and "benzine" to the more volatile portion of petroleum has led to great confusion between petroleum spirit and coal-tar naphtha, the most characteristic constituent of which is the hydrocarbon *benzene* or *benzol*. In this paper the author mentions several tests for distinguishing between the two bodies, the most important of which are the following:—

Petroleum Spirit, "Benzoline or Benzine," warmed with four measures of nitric acid of 1·45 sp. gravity the acid is coloured brown, but the spirit is little acted on, and forms an upper layer.

Coal-Tar Naphtha or "Benzol" is completely miscible with four measures of nitric acid of 1·45 sp. gravity, with great rise of temperature and production of dark brown colour.

These tests are capable of yielding quantitative results if the treatment with nitric acid be conducted in a small flask and an inverted condenser attached, to prevent loss of vapours. When action has nearly ceased, if the liquid be poured into a narrow graduated tube, the measure of the upper layer indicates with approximate accuracy the amount of petroleum spirit present. If the proportion of benzene is considerable, the nitrobenzene produced may not remain completely dissolved in the nitric acid, in which case it rises and forms a layer of a dark brown colour below the stratum of petroleum spirit. Nitrobenzene and petroleum spirit are readily miscible in the absence of nitric acid, but agitation with strong nitric acid dissolves out the nitrobenzene, a portion of which may rise and form an intermediate layer as above described.

By fractional distillation, the author found that the proportion of *heptane*, C_7H_{16}, present in commercial benzoline probably equalled, or even exceeded, that of all the other constituents.

On some Curious Concretion Balls derived from a Colliery Mineral Water, by Thomas Andrews, F.C.S.—The water on which these observations were made was collected from the "sump" of the Wortley Silkstone Colliery, a small pit situated near the "Bassett" or "outcrop" of the great Silkstone seam of coal, the samples being obtained during typical *dry* and *rainy* seasons. The water had percolated from the surface a distance of thirty-five yards, through strata, as indicated on the accompanying table.

The bottom layer in which the water lodged was the Silkstone seam of coal, here some five feet in thickness.

One noticeable feature of this water is that it always gives an acid reaction with blue litmus paper.

Several analyses of this water made at various times indicate that the chief mineral constituents of the water are, iron—calcium, magnesium, in the form of sulphates.

This water when heated quickly throws down a copious ochreous deposit. The deposit found in the engine boilers, after having used the water in them for steam purposes was of the composition given below.

The boiler residue from which this sample was taken consisted of an incrustation about *one inch* thick, which had adhered to the bottom of the boiler.

The incrustation was of a light reddish yellow colour in the bulk, it was very hard and tough, and not easily broken in pieces.

The iron work in connection with this colliery engine and boilers, in any way exposed to the action of either the acid water itself or *the steam generated from it*, becomes corroded and partially dissolved. The most effectual remedy against this corrosive action and deposit is that described in my letter to the *Chemical News*, June 15, 1877.

Some curious balls of mineral matter are occasionally found in the feed tank of the colliery boilers, which are supplied with this water. The water is pumped up from the engine pond into a cylindrical feed tank, and is there heated by the exhaust steam from the engine playing on its surface (not blowing through it). The water in this feed tank has an average temperature of 164° F.

It sometimes happens that during the short space of even two or three weeks, great numbers of these balls are formed, varying in size from about three and a half inches in diameter to five-eighths of an inch diameter, and in weight from about one and a half pound to a quarter of an ounce.

The author has many of these in his possession. They are perfectly hard and compact when taken from the tank, and are, no doubt, formed from the deposit thrown down when the mineral water is heated.

The action of steam playing on the surface of the water probably causes circular eddies, and when a nucleus has thus once been formed, it is easy to conceive of the gradual formation and consolidation of these balls.

The author suggests that the conditions of formation of natural nodules of iron ore, pyrolusite, &c., may be similar to those observed by him in the foregoing cases.

On the Detection of Milk Adulteration, by William H. Watson, F.C.S., &c.—From analyses of milk from various dairies, and by a comparison of the results obtained with circumstances existing as to the character and quantity of the food; nature of different cows; conditions and health of them at particular periods; and changes of the seasons of the year, the author concludes that cows' milk is subject to considerable variations in composition. He has found, in many instances, milk from well-fed healthy cows to contain as little as 10·5 per cent. of total solids, and from 8·5 to 9 per cent. of solids not fat. The results of other experimenters are compared, and it is then suggested that the present limits adopted by public analysts for genuine milk should be reconsidered.

SECTION C—Geology

On the Volcanic Products of the Deep Sea of the Central Pacific, with Reference to the "Challenger" Expedition, by the Abbé A. Renard and J. Murray.—The mineralogical and petrological researches on the sea-bottom of the Pacific area, extending from the Sandwich Islands to 30° S. lat., and having the Low Archipelago on its approximate centre, show that volcanic matter plays an important part there. It is present in the form of lapilli and of ashes spread in great abundance in the "red clay." These lapilli nearly all belong to the basaltic type, passing from the felspathic basalts to allied rocks, in which the vitreous base assumes greater and greater development, until it almost completely displaces the crystalline constituents of basalt. The fragments then become mere glassy rocks of the basic series, in which generally are still found crystals of peridote and numberless crystallites, which are sometimes grouped in opaque granules, or arranged regularly around the microliths of peridote. The forms of these volcanic fragments, which are often coated with manganese, their association with volcanic ash, and their lithological constitution, show them not to be derived from submarine flows of lava. They must rather be regarded as incoherent products, or lapilli, the accumulations of which in the Pacific form a series of submarine tuffs. One of the most remarkable facts elicited by the soundings in the Pacific is the large share

taken in these sedimentary deposits by palagonites, quite identical in lithological characters with those of Sicily, Iceland, and the Galapagos Islands. One may, in fact, call them glasses of the basic series, playing the most important part among the sediments of the Pacific, and consisting either of sideromelane or decomposed into a red resinoid substance. The small lapilli of two or three inches in diameter are cemented by zeolites, the crystalline forms of which are those of christianite. It is enough to indicate the presence of the easily alterable basic glasses, in order to show the source of the clayey matter with which they are associated, since it is known that wherever rocks of this type occur, there also decomposition into clay is observable.

Amongst the minerals present in the volcanic ash are rhombic tabular crystals of plagioclase, augite, magnetite, with a little sanidine or hornblende. It is also remarkable to notice that in these deep-sea deposits quartz grains are practically absent, in striking contrast to the coast-deposits. It is not, however, this fact which is most worthy of note, since it is not so unexpected as the formations of *zeolites* in the free state. The latter phenomenon takes place in the zone in question where minute fibrous radiated spherules are formed in the mud, possessing the crystallographic characters of christianite. Besides these zeolitic globules, there are other crystals of the same kind in the form of very minute prisms, occurring in such prodigious numbers that they make up about a third of the red clay. Crystallographically these microliths must be referred to those forming the zeolitic spherules. The authors regard them as belonging to one species. The formation of these zeolites and of the red clay in which they are developed, is easily understood if we bear in mind the lithological nature of the above-described basic tuffs and of their products of decomposition.

The Geological Age of the Rocks of West Cornwall, by J. H. Collins, F.G.S.—Mr. Collins endeavours to show that a large area of West Cornwall, hitherto mapped as Devonian, really consists of upper Silurian rocks; lower Silurian rocks underlie them, whilst a still older series occurs at several points on the coast—possibly the mica schists of the Lizard belong to this oldest series.

Geological Facts observed in Natal and the Border Countries, by Rev. G. Blencowe.—Mr. Blencowe describes the country near the border of Zululand. The rocks are sandstone, capped by trap, which often stands out in isolated hills rising 2,000 feet above the plain. Evidences of ancient volcanic action are noticed.

On "Culm" and "Kulm," by Prof. G. A. Lebour, M.A., F.G.S.—He suggests that the English word "culm" be retained as a local term for the culm measures of Devon and Somerset. Under the Germanised form of the name ("kulm") are now grouped a vast mass of carboniferous slaty beds which strike across Europe from Eastern Silesia to the westernmost point of Portugal; these beds represent, not the coal measures of England, but the carboniferous limestone and underlying beds.

On some Remarkable Pebbles in the Boulder Clay of Cheshire and Lancashire, by Dr. C. Ricketts.—The pebbles give evidence of having formed parts of moraines on land. As they occur at different horizons it is inferred that there must frequently have been an advance and retreat of glaciers, moraines being formed during the retreat of the glacier, which were carried forward into the sea when the glacier advanced.

Notice of the Occurrence of a Fish Allied to the Coccosteus in a Bed of Devonian Limestone near Chudleigh, by J. E. Lee, F.G.S. —This occurs (in the upper or middle Devonian) with clymenia, goniatites, and crinoidal remains, and therefore cannot here be a freshwater fish.

Evidence of the Existence of Palæolithic Man during the Glacial Period in East Anglia, by Sydney B. J. Skertchly, F.G.S., H.M. Geological Survey.—The object of this paper is chiefly to record the sections in which the author has discovered palæolithic implements beneath the chalky boulder clay in East Anglia.

The beds which yield the implements are a series of loams, clays, and sands, to which the author has given the name of Brandon Beds. They occur at the top of the middle glacial series of Messrs. S. V. Wood, jun., and F. W. Harmer, and underlie the chalky boulder clay or upper glacial of the above-named authors.

On Carboniferous Polyzoa and Palæocoryne, by G. R. Vine.—In this paper the author drew attention to the inadequate study that had been given to the carboniferous Polyzoa. During the last few years vast masses of shales, containing Polyzoa and other remains have been brought to light, but none that he was acquainted with excelled in richness the Hairmyres *débris*. Here the specimens were well preserved and the characters of the several species were almost perfect.

The author considered that it was too early yet to draw up a classification that would be satisfactory to all naturalists. Attempts had been made to do this, but many details had to be furnished that could only be furnished after close study. Besides the *Fenestella*, other genera were alluded to in the paper, such as *Cenopora*, *Rhabdomeson*, *Hyphasmapora*, *Glauconome*, and *Diastopora*; but these are being studied analytically, and further details of their structure will be brought forward in a future report.

Palæocoryne was next alluded to, and the author said that he had identified all the species and forms of Palæocoryne that had been figured by Dr. Duncan in his various papers; but the conclusion the author had arrived at was—that these so-called organisms were neither hydroid, as was supposed by Dr. Duncan, nor foraminiferal, as was suggested by Dr. Allman. All the forms were referable to species of *Fenestella* and *Polypora*. Although this opinion was given with some confidence the author was not prepared to say at present that the whole of Dr. Duncan's views were illusive. There can be no doubt but that the forms *P. scotica* were really infertile processes; but *P. radiata* had presented so many peculiar details to the author, that until he had satisfied himself as to the nature and purpose of this structure in the polyzoary of the Polyzoa, he was not prepared to substantiate that Dr. Duncan had given an erroneous judgment, although *P. radiata* may turn out to be after all a portion of *Fenestella* and not a parasite.

On the Replacement of Siliceous Skeletons by Carbonate of Lime, by W. J. Sollas, M.A., F.G.S., &c.—The author gave an account of certain calcareous fossil remains which exhibit, both in gross and minute structure, a close resemblance to certain existing siliceous sponges, and which differ widely from any known form of calcareous sponge. The natural inference appeared to be that the calcareous fossils were once siliceous sponges, the siliceous parts of which had undergone replacement by carbonate of lime. The alternative view that the fossils were originally calcareous, and that they represent an extinct group of Calcispongia, was discussed and shown to present far greater difficulties to the zoologist than the inferred mineral replacement offered to the chemist. Siliceous sponge spicules were stated to be remarkably soluble, yielding readily to the attacks of minute boring algæ, and undergoing solution in sea-water soon after the death of the sponge which possessed them.

The radiolaria of the carboniferous limestone were likewise regarded as having once possessed a siliceous composition, which they had since exchanged for a calcareous one.

On the Foundations of the Town Hall, Paisley, by M. Blair.—Dolerite underlies the boulder-clay there, and is probably the source of boulders of a similar rock which occur in the drift, and which have hitherto been considered as strangers to the neighbourhood.

On "Ostrakocanthus dilatatus" (gen. et sp. nov.), a Fossil Fish from the Coal-Measures South-east of Halifax, in Yorkshire, by J. W. Davis, F.G.S.—This is an ichthyodorulite nearly $1\frac{1}{2}$ inches long, and $\frac{3}{4}$ inch broad at the base. From the base the diameter diminishes rapidly, and at half an inch from the apex it is only ·15 of an inch. It remains of this size to the apex, and ends in a blunt point. The upper part is smooth, with hard ganoid covering. The lower part is longitudinally furrowed, increasing by bifurcation towards the basal end. At first sight it somewhat resembles the *Byssacanthus* of Agassiz, and also the spine of *Ostracion cornutus*, but the similarity disappears on closer examination. From the spine and its mode of attachment it is probably a representative of the Teleosteans during the coal period.

SECTION D—BIOLOGY

Department of Zoology and Botany

On the Capreolus or Spermatophore of some of the Indian Species of the Helicidæ, by Lt.-Col. H. H. Godwin-Austen, F.Z.S., &c.—The author points out the importance of the examination of the animal in many genera of the Helicidæ, and thus to obtain better characters for specific distinction than are often presented by the shell alone. The organ first discovered and described by Lister in 1694 is treated of, and the views of later naturalists al-

luded to. Many different forms of the spermatophore found in Helices from Eastern Asia, are shown and the position of the organ in the generative system of *Helicaria magnifica* from Burmah is described.

On Budding in the Syllidean Annelids, chiefly with Reference to a Branched Form from the "Challenger," by Dr. W. C. McIntosh, F.R.S.—Propagation by budding is a prevalent feature amongst the Cœlenterata, the organisms assuming in many cases a dendritic appearance, so that the name of sea-trees given to them by our fishermen is by no means inappropriate to their external contour. A similar condition is seen in many of the Polyzoa, and in the creeping stolons of *Clavelina* and *Perophora*. In the sub-kingdom Vermes, again, naturalists have been long familiar with a mode of propagation by division or fissiparous development. Thus O. F. Müller describes two kinds of budding in the fresh-water *Nais proboscidea*, and gives an account of the same process in *Nereis prolifera*. Amongst others, De Quatrefages and Frey and Leuckart in the same species; Milne-Edwards in *Myriandra*; Sars in *Filigrana*; O. Schmidt in *Nais microstoma* and *Filigrana*; Max Schultze, R. Leuckart, and Traube in the former species; Alex. Agassiz in *Autotytus cornutus*; Schmarda in *Catenula*; and Lankester in *Chætogasta*, show how widely this mode of development has been recognised. The feature that mainly concerns us at present in regard to these descriptions is the fact that a new animal is produced in a line with the old by various modifications of budding. In no instance is there any approach to a branched condition by lateral offshoots from either parent stock or bud. As an example of one of the best known marine forms, the account of *Autolytus cornutus* by Alexander Agassiz may be cited. This species exhibits a kind of alternation of generation, the parent stock (which is a sexual) giving rise posteriorly to male and female buds which differ much in appearance from each other. The latter produce ova, which by and by develop in the peculiar body-sac into a swarm of parent stocks with which the cycle commenced.

The discovery of a species (*Syllis ramosa*) of the same family (*Syllidæ*), which forms an intricate series of branches by lateral budding of the parent stock, by Sir Wyville Thomson in a hexactinellid sponge from Zebu, is one of the remarkable results of the *Challenger* expedition.

A detailed account of the animal then followed, and the remarkable absence of all trace of a head prominently noticed.

Embryology of Gymnadenia conopsea, by F. Marshall Ward. —The researches of the last two years, especially of Strasburger[1] and Warming,[2] and also of Vesque,[3] have yielded results sufficiently at variance with the older ones to warrant a serious reconsideration of the whole question of homologies. The main points may be put somewhat as follows:—

The embryo-sac is not the result of simple enlargement of one cell; a cell of an axial series of the ovule enlarges and cuts off two or more cells from its apex—the remainder becomes the embryo-sac,[4] and causes dissolution of the others as it enlarges, their remains persisting as refractive caps for some time. The protoplasmic contents of the embryo-sac separates into two chief masses, which pass to the opposite ends of the enlarging sac, a large vacuole forming between. Each mass then suffers division into four by planes cutting one another at right angles. In this way eight nucleated masses of protoplasm without cell-walls arise, three of which remain at each end of the embryo-sac, while one from each end wanders towards the centre of the sac and there fuses with its neighbour to form the nucleus of the sac.

Of the three anterior nucleated masses, two become elongated, fit into the top of the embryo-sac as the "Gehülfinnen," or "synergidæ," of Strasburger, and are probably what Schacht described as the "filiform apparatus"; their function is somewhat obscure, but appears to be related to the act of fertilisation between the end of the pollen-tube and the third nucleated mass, which has rounded off as a large bright egg-cell or ovum, and is suspended from the base and sides of the "Gehülfinnen."

The three posterior masses may not become completely isolated, or they may remain passive, or some may disappear, or they may multiply by division. Where endosperm is formed they appear to enter into its formation.

The author finds in Gymnadenia,[5] Butomus, Alisma, Anthericum, and Ranunculus ovules, confirmation of these views.

[1] "Ueber Befruchtung u. Zelltheilung," and "Die Angiospermen u. Gymnospernem."
[2] *Ann. des Sc. Nat. Bot.*, 1878. [3] *Ann. des Sc. Nat. Bot.*, 1878.
[4] Vesque, however, thought a fusion of at least two superposed cells produced the embryo-sac.
[5] Strasburger has partly worked this, so far as the first divisions of the embryo-sac mother-cell are concerned. He also gives figures of Anthericum. Vesque's account of Butomus is not supported by the author's drawings.

With reference to Warming,[1] and Vesque's[2] view that the origin of the embryo-sac is comparable to that of the mother-cell of pollen, and that the eight nucleated masses arranged in fours are therefore homologues of pollen grains (*i.e.*, spores), the following facts are of importance, as failing to support the theory:—1. The diffluent cell walls which form between the cells cut off by the embryo-sac mother-cell, are in no way important on account of their resemblance to the diffluent walls in pollen formation; they also resemble the diffluent walls formed in the suspensor (pro-embryo), or any other organ rapidly absorbed, &c. 2. The division into fours by planes crossing at right angles is common to many other processes besides pollen formation, *e.g.*, the embryo itself. 3. Vesque's view as to the embryo-sac arising by fusion of several cells is not supported by the existence of the remains of the *two cap cells* above the embryo-sac—the remains of the supposed fusing cells.

Comparison of the Effects of the Frosts of 1860-61, *and of* 1878-9, by E. J. Lowe, F.R.S.—The greatest cold of 1860 exceeded that of last winter by 10°; it was 6° below zero in 1860, and 4° above zero in the late frost.

The present paper records the great difference in the effects in the two frosts at Highfield Honse, Nottingham:—

Name.	Frost of 1860.	Frost of 1878.
Acacia (long spined)	Slightly injured	Many boughs killed and was a month later coming into leaf.
Elm (broad leaved)	Uninjured	Three-quarters of boughs killed back at least 2 feet.
Bay (sweet)	Killed to the ground	The ends of the shoots only killed and all the leaves.
Deodar cedar	Became deciduous, otherwise uninjured	Not injured.
Arbutus	Killed to the ground	Half the branches killed, the others injured.
Aucuba	,, ,,	Uninjured.
Pampas grass	Killed	Killed.
Araucaria imbricata	Killed to where buried in the snow	Uninjured.
Yew	Slightly damaged	Slightly damaged.
Wellingtonia gigantea	Much injured	,, ,,
Evergreen oak	Many killed, all became deciduous	Uninjured.
Ivy	More or less injured	More or less injured.
Fennel	Uninjured	All killed.
Sage	Killed	Uninjured.
Roses (standards)	All killed	Many killed, nearly all injured.
,, on their own roots	Many killed	Uninjured.
Retinospora obtusa	Killed	,,
,, *squamosa*	,,	Slightly injured.
,, *leptoclada*	—	Uninjured.
,, *ericoides*	—	,,
,, *filifera*	—	,,
,, *plumosa*	—	,,
,, *plumosa argentea.*	—	Slightly injured.
Juniperus excelsa	Killed on the north half of the tree	Uninjured.
,, *chinensis aurea*	—	,,
Phormium tenax	Killed	Only killed to the ground.
Eugenia ugni	,,	Half the branches killed
Yucca gloriosa	,,	Slightly injured.
Cineraria maritima	,,	Killed.
Laurel, common	Many killed to the ground	Uninjured.
,, Portugal	Nearly all killed	,,
Holly	Most killed in the branches to the height of 7 feet	,,
Thuja aurea	Mostly killed	Slightly injured.
Cork tree	Killed	—
Deutzia gracilis	Scarcely injured	Uninjured.
Quince	Killed	—
Yew, golden	Slightly injured	Uninjured.
Pinus insignis	Killed	,,
,, *pigmy*	Slightly	,,
,, *menziesii*	Became deciduous, and had no leaves for a year	,,
,, *morinda*	Slightly injured	,,
Laurustinus	All killed	,,
Abies Nordmanniana	Uninjured	Lost half its leaves and some boughs.
Walnut	Boughs killed and one tree	Uninjured, except a want of vigour; leaves only half the usual size.
Apples	—	Leaves small, fruit scarce and remarkably small.

[1] *Ann. d Sciences Nat.*, 1878. [2] *Ann. d. Sc. Nat.*, 1878.

The above will sufficiently illustrate the effects of the frosts in two severe winters.

It is worthy of remark that instead of cold killing the slugs and various pests of plants, they were never known so numerous. Many hardy plants in pots were killed, such as ivy, *Pteris aquilina*, &c., when they escaped if plunged in the ground.

Recent Additions to the Moss Flora of the West Riding of Yorkshire, by Charles P. Hobkirk, F.L.S.—After treating of the work of the Yorkshire Naturalists' Union, in investigating the fauna and flora of the country, the author particularised some of the chief species found since 1873, and gave the history of them, viz., *Seligeria tristicha* at Littondale; *Aulacomnium turgiaum* at Whernside; *Fontinalis gracilis* at Malham Cove; *Plagiothecium nitidulum* at Penyghent, &c. Four lists were appended to the paper, viz.: (1) New species, 48; (2) Species found in fresh localities, 142; (3) Localities previously known, but not recorded, 29; and (4) Species inserted in error in previous list, 8; making the total number of species now recorded for the Riding, 327.

Department of Anthropology

Flint Implements from the Valley of the Bann, by W. J. Knowles.—I have obtained within the last three or four years, from the banks of the River Bann, a series of flint weapons or tools which differ considerably in type from the ordinary flint implements of the North of Ireland. They have been obtained from a deposit of diatomaceous earth used for brickmaking, near the town of Portglenone, and are of two types. That which is most numerous appears to have been been made by splitting up nodules into halves and quarters, and then forming these into rude pointed implements by a process of coarse chipping. This kind numbers upwards of fifty, and they all agree in having a cutting point and thick base for holding in the hand. They are as a rule long, narrow, and of a cylindrical form rather than broad and flat, but some of the latter kind occur. Some of the largest are 7 or 8 inches long and from 2 to 3 inches broad at the base, and there is one fine implement of the flat kind, very like the triangular palæolithic implements, which is 6 inches long, nearly 4 inches broad at the base, and 1½ inches thick. Dr. Evans, in "Stone Implements and Ornaments of Great Britain," mentions that he has found implements of palæolithic form on the shores of Lough Neagh, near Toome, and I have also found them there myself, but as Toome is only a little farther up the Bann, and the diatomaceous earth is found there, I believe they have been derived from that deposit by denudation.

The second set of objects may be described as large triangular flakes with a central rib down the back, and having the base wrought into a tang. In the Catalogue of the Royal Irish Academy this form of implement is represented in Fig. 3, the tang being looked on as the first step of development into arrow- and spear-heads; but I am of opinion that instead of showing a step towards greater perfection, these were perfect implements of their kind, and also manufactured specially for use about rivers.

There is no means of determining the age of these objects except we form some sort of estimate from the fact of their being found in a deposit underlying peat. If they are of neolithic age they are very interesting from being confined chiefly to a river valley, and not being obtained where other neolithic implements are found in abundance. This fact would, I think, suggest a reason for the large triangular flints of palæolithic age being chiefly confined to the old river gravels, while the implements of the same age from the caves are so different. The implements of the pointed kind in all cases might not be for general use, but chiefly for the river valleys. They may probably have formed weapons for attacking the larger animals when they came down to drink, but the theory that they were used for breaking holes in ice I think a very likely one. I believe the tanged flakes were used mounted probably for spearing fish, as suggested by Dr. Evans in "Archæologia," vol. xli. p. 401.

On the Relations of the Indo-Chinese and Inter-Oceanic Races and Languages, by A. H. Keane, M.A.I.—The conclusion arrived at by the author, is, that, excluding the dark races, there are in the Indo-Chinese and Inter-Oceanic area two fundamentally distinct racial types only—the yellow or Mongolian, and the fair or Caucasian; and corresponding to them two fundamentally distinct forms of speech only—the monosyllabic spoken *vario tono*, and the polysyllabic spoken *recto tono*. All the rest is the outcome of incessant secular interminglings.

Mr. Sydney B. J. Skertchly, F.G.S., H.M. Geological Survey, read a paper *On the Evidence of the Existence of the Palæolithic Man during the Glacial Period in East Anglia*. The object of the paper was chiefly to record the sections in which the author had discovered palæolithic implements beneath the chalky boulder clay in East Anglia. He said:—"The beds which yield the implements are a series of loams, clays, and sands, to which the author has given the name of Brandon Beds. They occur at the top of the middle glacial series of Messrs. S. V. Wood, jun., and F. W. Harmer, and underlie the chalky boulder clay or upper glacial of the above-named authors. They have yielded palæolithic instruments in many places, but only those will be described in which the chalky boulder clay overlies the Brandon Beds at the present time. Near Mildenhall, on the River Lark, in Suffolk, two sections have yielded implements. They are at Warren Hill and Mildenhall Brickyard. The section at Warren Hill is as follows:—1. Sandy soil, &c., two feet. 2. Chalky boulder clay six feet. 3. Gravel four feet. 4. Loamy clay four feet. 5. Boulder clay six feet. 6. Chalk. This spot has yielded great numbers of flakes and many implements. It was originally described by Professor Prestwich, but the boulder clay has only recently been exposed above the tool-bearing loams. At Mildenhall Brickyard the section is—1. Sandy soil one foot. 2. Chalky boulder clay six feet. 3. Loam ten feet. 4. Chalk. From this place many implements and flakes have been obtained. They occur in the loam. Culford in Suffolk: The Brandon beds are here dug under fifteen feet of solid boulder clay; from these I obtained two flakes. West Stow, in Suffolk: Boulder clay overlies, underlies, and wraps round the Brandon beds at this place; some well-worked implements have been obtained, one of which was dug out by the author. Brandon: Near Brandon the same beds are being dug beneath boulder clay, and have yielded very good implements. The peculiarities of the implements are pointed out, and the mode of distinguishing them from specimens from the gravels is indicated. The author in this paper merely desires to emphasize the fact that from several sections he has himself dug out palæolithic implements from below tough, undisturbed chalky boulder clay. These proved the existence of man in these districts previous to the glacial periods.

The Chairman said that if Mr. Skertchly's facts were sound and his inferences well warranted it was obvious to all the matter was one of the greatest importance. He invited discussion.

After some remarks from Dr. John Evans, Prof. W. Boyd Dawkins (Manchester) said there was no evidence that the glacial period was to be looked on as a dividing line in classification. He fancied that all the animals that were living after that period of extreme cold had passed away appeared in Europe before that cold was felt, and he could not therefore, look on the glacial period as a hard and fast line. It seemed to him if they applied that consideration to the examination of the question of the antiquity of man there was no *à priori* reason for supposing that man was not here in the pre-glacial age. Seeing that animals were living in Europe before the cold period arrived at its maximum, it was probable that man was here too. Man was living in the south of this country when the area north of the Thames was submerged—when the sea there was bearing icebergs which were accumulating the boulder clay.

Sir John Lubbock, said that as geologists they must be careful before they came to any definite conclusions on a matter of this importance. He confessed that after listening to the paper which they had just heard he felt considerable difficulty in resisting the conclusions which Mr. Skertchly had drawn from the facts. He thought there could be no doubt that the implements before them were the work of man.

Professor Huxley said that without the slightest desire to discourage the excellent efforts Mr. Skertchly had made, he confessed he could not attach any great importance as to whether those particular deposits were post-glacial, inter-glacial, pre-glacial, or how. There was not the slightest doubt that at the end of what was commonly recognised as the tertiary period there was a time in which the climate of this country became extremely severe—there was a great formation of ice. There was no doubt that the animals which existed in this part of the world immediately before that deposit, were practically the same as those just after. If they looked at the glacial epoch as a period

of duration of animal life—the period it occupied was totally insignificant in regard to that which they would require for the evolution of man to his present state. There could not be the slightest reason for supposing that pre-glacial man was in any way different from post-glacial man. No doubt, whatever habits of life were adopted during the cold period, were adopted before that cold fairly set in. As the people lived like Equimaux during the whole of the cold period, and for some time afterwards, he could not see why they should not have lived in that fashion for some time before. There could not be a doubt in any reasonable man's mind, that the remains of man discovered in the older part of the glacial deposit were the same as those in the new. The evidence Mr. Skertchly had brought forward was very satisfactory, but he confessed he did not see why it should not be so.

Mr. Skertchly read a paper *On a New Estimate of the Date of the Neolithic Age.*—The Fenland occupies an area of 1,300 square miles around the great bay of the Wash. The surface of the inland portions consists of peat, and that of the seaward parts of marine silt. This silt is still in process of deposition, and the land is consequently gaining upon the sea. From the time of the Roman occupation, at least, banks have been successively erected to reclaim the newly-formed ground; and as the dates of these banks are known, very accurate estimates can be formed of the rate at which the deposition is going on in different parts. The maximum rate is fifty-nine feet per annum, and four miles of new land has been formed since the oldest banks were erected. These banks are generally ascribed to the Romans; but they are probably British. In this estimate they will be taken as Roman, in order that the age may not be over estimated, and the maximum rate of deposition will also be used as giving the minimum of time. The geological evidence shows that as the silting went on, and the area become converted into land, peat grew and gradually spread over the newly-formed ground. But in process of time the climate became unfitted for the growth of peat, which gradually lost its vigour, and finally ceased to form. Hence a wide stretch of silt land borders the Wash, upon the surface of which no peat has ever formed. The peat died upon its eastward march; the silt still travels on. The nearest approach of the peat to the banks along the line of most rapid accumulation is twelve miles distant therefrom. The age of this, the newest peat in the Fenland, can be thus determined. Between the "Roman" banks and the sea lie four miles of silt, which has taken 1,700 years to accumulate. Between these banks and the sea lie twelve miles of silt, which at the same rate of formation would take 5,100 years to accumulate. Adding 5,100 to 1,700 years, we have 6,800 years as the least possible age of the newest peat. This peat has yielded many neolithic implements, hence we may assume that 7,000 years will take us back into the neolithic age. The coincidence of this estimate with the two Swiss ones above-mentioned is remarkable. These results do not, however, give us the date of the introduction of the neoliths into Europe, for neither in the Swiss nor English localities are we sure that the neolithic relics belong to the early part of the neolithic age. The author, indeed, has recently obtained evidence of neolithic handiwork in Fenland peat of far greater age than that described, the peat bed underlying silt more than 7,000 years old. He is inclined to think that the neolithic age in England began at least 10,000 years ago, and perhaps 20,000 years; but that it does not approach the close of the glacial epoch seems to be shown by the fact that the older Fenland beds (themselves post-glacial) do not contain human relics.

Commander Cameron read an interesting paper giving a detailed account of the *Manners and Customs of the People of Urua, one of the largest Native States in Central Africa.* This particular race maintained many places in which religion was centralised. Kasango, the king or principal chief, was not merely a secular chief, but was also intimately mixed up with the religion of the people. He claimed divine praise, and at his death was buried with savage rites, and all his wives except one were slaughtered at his grave. This one remained to be the pythoness of his successor, and the spirit of the chief at his death was supposed to be transmigrated into the body of his successor. An idol was preserved in the middle of a dense jungle. He had for a wife one of the sisters of the reigning sovereign. Around about the jungle were the huts of a numerous class of priests, who received the tribute collected for that class of people. The only person allowed to sacrifice to the idol or to visit him except the idol's wife was the sovereign of the country. There was a numerous class of wizards who carried about with them small idols and a large stock-in-trade in charms, which they sold. Many of them were ventriloquists, and it often happened when they were consulted by the natives questions were asked which were communicated to the idol, and then the wizard, by the exercise of very poor ventriloqnism, made the idol return an answer to the question put. The caste was very clearly defined in this race. The chief allowed none of his subjects to sit down in his presence without permission, and he seldom accorded it. No one of a lower grade could sit down in the presence of one of a superior grade. The customs in eating, drinking, and cooking were various. They declined to eat in the presence of each other, and, although fond of the native beer, they would not drink it while anybody was looking on, although it was sufficient to hold up a cloth as a screen. All the different castes and ranks were marked and distinguished by their dress. The attire was very simple, consisting usually of an apron. They were not a hairy race, but managed to grow their beards very long, and they plaited them after the manner of a Chinese pig-tail, winding up with a ball of dirt at the end to make it hang down straight. The women were tattooed most extensively. The means of communicating news was by drums and messengers. The men could run very fast. One man, for instance, brought him a message from the king, having come a distance of between 50 and 60 miles in a period of six hours. By means of certain beats on the drum messages could be sent immense distances, and answers immediately returned. In time of war the king could send messages to a great distance, either to bring up his forces at once, or to say that he was returning and that they were to go back.

Major Serpa Pinto read a paper *On the Native Races of the Head Waters of the Zambesi.*—He said they there found people whose complexion, as compared with his, then bronzed with an African sun, was white, yet they were negro in feature. There were also mixed races in that part of the country, with complexions of a whitish cast, yet with negroid features. The whole matter seemed to indicate in a most puzzling way the mixture of races. In the Bihé district, that portion of the population had, for the most part, made its appearance during the last century. It was not a pure African, but probably a mixture with the races which came over for elephant hunting purposes. The pure African type, of course, was the flat nose, large lips, and frizzled hair; but there had been some modifications in this instance with regard to feature. He declared that he had seen girls in that part of the country who, if their complexions had been more like that of the Europeans, would have passed for beauties here.

M. Brazza read a communication *On the Native Races of the Gaboon and the Ogowé.*—Major Pinto, he said, had spoken of races having European characteristics. He was of opinion that those people had come from the North of Africa, because under the name of Ubamba he had found races very much resembling them to the south of the Congo. The negroes Major Serpa Pinto saw were probably the advanced guard of an invasion which had overrun the country to the east of the Gaboon. Stanley spoke of a great emigration, very much resembling what had taken place among the Fan cannibals. There had been much talk indulged in adverse to the cannibal races of this part of Africa. Du Chaillu, who had visited for one day only one of the Fan villages, had given a description of this race which had been too much influenced by accounts he had received from a tribe at war with the cannibals. He had said that in their villages he had found quarters of human flesh exposed for sale; that they killed and ate their prisoners of war, and that they sold the bodies of their own dead who had died of disease to their neighbours. M. de Brazza denied the truth of such accounts. As a proof that the Fans had kindly and generous sentiments he told how a Fan chief had been kind to him when he was obliged to leave his people sick in the bush. He owed his life to the Fan chief, and he should always be grateful to him and his people. He wished therefore to do all he could to remove the prejudice against the Fans which had been excited by Du Chaillu. They were a very generous, courageous people. It was true they were cannibals—that they ate their prisoners of war; but it was with them a religious idea,' for they believed that in eating the heart of a brave man the courage of the dead passed into themselves. M. de Brazza also gave an interesting sketch of the Akkas, a dwarf race he found scattered up and down among the different peoples, like what the Jews or the gipsies were in Europe. The height of the Akkas was from three to four feet.

Mr. V. Ball, M.A., of the Geological Survey of India, in continuation of some remarks make on this subject at the last meeting of the Association in Dublin, gave an account of the results at which he had since arrived from an examination of all the available data. These were that the three classes into which the stone implements might be grouped occupied independent geographical tracts which overlapped one another towards the centre of the peninsula. The geographical tracts characterised by the prevalence of one or other of the particular forms when laid down on a map showed a remarkable coincidence with the limits of the areas of distribution of the non-Aryan races belonging to the several families whose waves of imigration had contributed to form the lower strata of the population. Thus the manufacturers of the polished Celts were identified with the Kolarian races who entered India from the north-east and Burmah. On the other hand, the manufacturers of the flakes and cores of flint, &c., appeared to have entered the peninsula from the north-west, and to have belonged to the Dravidian family. The identity of the manufacturers of the chipped quartzite implements which were found in Southern India, was less clear, but suggestions regarding it were also offered by the author.

SECTION E—GEOGRAPHY

Mr. C. E. D. Black, read a paper *On the Geography of the Upper Course of the Brahmaputra.*—With especial reference to a recent important exploration of the easternmost portion of its course, made by one of the native explorers attached to the Indian Survey Department of this piece of work, though executed in 1877, no description had reached Europe, and its communication for the first time to the British Association was therefore a geographical event of very great interest. Mr. Black commenced by tracing the topography of the great Sanpee river from its source 15,000 feet above sea level in Western Tibet, over lofty plains, past the towns of Janglache, Shigatze, to the furthest eastern point to which it had been traced by the famous Indian explorer, Pundit Nain Singh, noticing *en route* the remarkable hot springs in the valley of one of the northern tributaries, the Shiang-chu, and the various rivers which join it on the left and right banks. The plain and city of Lhasa, the residence of the Dalai Lama and of the Chinese governors or agents, was described, as well as the amusing incidents accompanying the transit of the river on the occasion of that eccentric traveller, Mr. Manning, proceeding to Lhasa. From Chetang eastward commenced the new work of the explorer, N——g, who had been commissioned by General Walker, the Surveyor-General of India, to explore the course of the Sanpee for as great a distance as possible. Crossing to the north bank of the river, he followed it for a distance of 30 miles, nearly to the confluence of the Milk-chu, a small stream. Here he diverged to the north-east, making a detour of 50 miles, while the river wended its way for 20 miles through impenetrable mountains. The most remarkable feature of the exploration was the discovery that the river made a huge bend northwards before commencing its south-eastern course into Assam. This bend was actually surveyed by the explorer. From his furthest point to the highest known point of the Dihong, an unsurveyed gap of about only 100 miles now remains. Mr. Black concluded by pointing out that this great bend, which was previously unknown, now leaves room for a northern feeder of the Subansiri, and thus accounts for the large bulk of the latter river. Mr. Black also cited some important corroboration of this new fact, afforded by the Abbé Desgodins' researches, and by the recent measurement of the discharges of the large rivers of Assam by Lieut. Harman, R.E.

Prof. P. J. Veth, president of the Dutch Geographical Society, contributed a paper, giving interesting details of the *Dutch Expedition to Central Sumatra.*—The most important result of the expedition was the gain in knowledge of the great extent and capabilities of the Batang-Hari, which is found to be about 210 miles in length in a straight line, and over 490 miles following its windings, being in fact larger than the Musi or Palembang, hitherto considered the only large river in Sumatra. It is practicable for small prahus, used in transport of merchandise, for 480 miles; and the steam launch drawing 3½ feet could navigate it for 370 miles, both these distances far exceeding the navigable portion of the Musi. Its tributaries are also navigable for boats, and one of them at least for the launch. The population of its district as a whole is scanty, yet there are numerous villages close to each other; cattle abound in the highlands, and coffee is largely cultivated in Karinchi. The importance of the river as a highway for the eastern parts of the West Coast Government and the inland districts of Jambi and Karinchi does not therefore merely depend upon its fitness for transport of coal from the Ombilin Valley.

A paper by Major Pinto was read *On his Journey across Africa*, in which, though he did not tell much that was new of his exploration, he referred to one or two points of some scientific importance. He was desirous of calling the attention of the Section to the manner of determining the longitudes by the eclipses of the satellites of Jupiter, and he suggested a means of overcoming an obvious difficulty. Let it be resolved, he said, that in one of the many official observatories that had the support of Europe the eclipses of the satellites of Jupiter be studied without interruption, and the solitary explorer, lost, so to speak, in the enormous solitudes of the dark continent, when he in the obscurity of night saw the little brilliant speck disappear, would know that in a position perfectly determined some other person likewise at that same moment saw the small satellite disappear, and he will have the consciousness that on his return to Europe he will meet with the necessary elements to determine as many strictly correct longitudes as were the observations he might have made. When the planet was in conjunction the telescope might be turned toward the star that hid itself, or by making a series of apozenites of the moon they would obtain their longitudes. Any explorer of tropical Africa once provided with the aba and a telescope of 4 feet focal distance would find himself in a position to determine two of the co-ordinates and any variations of the compass. Major Pinto further recommended the hypsometer and aneroids for altitudes. Major Pinto gave a short *résumé* of the meteorological conditions of the Zambesi. He explained that the banks of the upper part of the river were of a fine and white sand of a remarkable character; when trod upon it produced a queer sound resembling somewhat the crying of a young child. The range of the Catongo mountains was well peopled on the westward, and it was there the Barotzes made their plantations, which consisted of maize, sweet potatoes, pumpkins, and mandisca. The great plain was not availed of for agriculture. Around the lakes and some other places a kind of grass grew, upon which thousands of oxen might be seen grazing. The Luinas followed the calling of shepherds. Horses could very easily be bred there, and the Barotzes possessed a splendid specimen of hounds, with which the natives hunted the antelope. The human race at present populating the country was a true mixture of the Lobares, Luinas, and Janguellis. The makalotus had now disappeared completely. Polygamy prevailed, and, contrary to what occurred in most other tribes, women who were held to be noble enjoyed high consideration and were sometimes invested with the exercise of public functions. The Barotzes possessed a tolerable quantity of firearms, but their natural arm was the assegai. They were rather industrious and good tanners, but did not use the knife, doing all their work with the blade of the assegai.

Several important papers on Afghanistan were read in this section by officers and others who had been with the English army in the recent Afghan war.

Mr. William Simpson, the special artist of the *Illustrated London News*, read a paper, entitled *Afghan War—the Jellalabad Region.*—The tendency of his explorations, beyond his own proper sphere as an artist, was rather archæological than geographical. No account of the Jellalabad Valley would be complete without some notice of the Buddhist remains to be found there. He was aware previously of the existence of these remains, but what astonished him was the vast quantity of them still to be seen. On all sides are extensive mounds and heaps, that being the condition in most cases of these remains. Here and there structures may be found, which, although in ruins, yet bear on them some traces of architecture. One point is apparently clear, that in the Buddhist period the population of the Jellalabad Valley must have been much more numerous than at present, and that the area of cultivation must have been also more extensive. Major Cavagnari supplied the author with a working party to make excavations at the Ahin Posh Tope, about a mile south from Jellalabad. The principal object was to explore the architectural details of the remains, but while thus engaged, the author penetrated, by means of a tunnel, cut for about 45 feet through solid masonry, to the central shell of the shrine, and found along with what were most probably the ashes of some Buddhist saint of high repute, twenty gold coins,

each about the size of a sovereign. Seventeen of these were Bactrian, or Indo-Scythian; and three were Roman.

Major Campbell described the *Shorawak Valley and the Toba Plateau in Afghanistan*.—The Shorawak valley had never been visited by Europeans before the recent campaign. It is a narrow strip of flat country lying between the desert on the west and north-west, and a range generally known as the Sarlat Hills to the east. Its total length is about 40 miles, with a width of 10 miles at the northern end; and it is 3,250 feet above the sea. The head of the valley, to the north, is closed in by the southern spurs of the Khwaja-Amran range of mountains, which nearly join the north-western spurs of the Sarlat Hills, only leaving a gap of about a mile through which the Lora river runs into the valley. The valley is thickly populated, and crops of wheat and barley are raised. Major Campbell suggested that Shorawak was once a lake, which was gradually silted up by deposits from the Lora, and this seems to account for most of the phenomena. The river, after flowing through the valley, is swallowed up in the sand of the desert. The Toba tableland is at the north-eastern extremity of the Khwaja-Amran range of mountains. The general elevation is over 7,000 feet. Major Campbell gave an interesting account of this plateau and of its inhabitants. It will probably form an excellent hill sanatorium for the troops stationed in the Pishin Valley. The climate of the plateau in summer is very pleasant.

Papers were also read *On New Routes to Kandahar*, by Captain Haldich; *On Surveys Around Kandahar*, by Captain M. Rogers, R.E.; and *On the Orography of the North-West Frontier of India*, by Mr. Trelawny Saunders.

Mr. Black read a paper, which had been contributed by Mr. J. O. N. James, deputy superintendent of the Surveys of India. The object of the paper was to sketch out, in a concise manner, the nature of the work in progress and already performed by the Indian Survey Department, and to point out its practical utility. During the administration of Sir Henry Thuillier, late Surveyor-General of India (1861 to 1877), an area of not less than 290,000 square miles was surveyed and mapped, including the wildest and least known tracts of India. This enormous area, more than double the size of Great Britain and Ireland, was surveyed in sixteen years at an average cost of *2l.* per square mile. Also an area of 493,000 square miles was completed on the village survey system on a scale of four inches to the mile, and 12,281 square miles by cadastral measurement on a scale of 16 and 32 inches to the mile; making an aggregate of 505,574 square miles, considerably more than double the area of France. The revenue surveys comprise a great portion of Bengal and Assam, all Oudh, part of the North-West and Central Provinces and Bombay, nearly all the Punjab, and all Sind. There is not a single official in India who does not possess maps of the portion of the country included in his jurisdiction, which are suited to every present requirement. The maps issued by the Surveyor General's Department are also utilised by engineers in the construction of public works, by the foresters for conservancy purposes, by mining companies, planters, holders of estates, and by every branch of the civil and military services for purposes too numerous to detail.

SECTION F—Economic Science and Statistics

Papers were read in this Section by Dr. Gladstone *On Elementary Natural Science in the Board Schools of London*, by Mr. Miss, of the Sheffield School Board, on a similiar subject, and by Mr. Hance, of the Liverpool School Board, describing the successful efforts made by them in science teaching. In the interesting discussion which followed, Mr. F. Wilson observed that what they required was the introduction of the science of perception. A child could see a thing and not always perceive it, therefore it was most essential that they should teach scholars to perceive and so obtain a system of order.

Dr. R. Wormell remarked upon the importance of having teachers who knew something about the teaching of science in the beginning, and spoke of the necessity of a college where teachers could be instructed in order to carry on the work of scientific teaching. There were 1,600 young men entering the training colleges every year, and at least 100 of these would do better as teachers of science than of other subjects. Scientific education ought to find its way into all schools from the earliest stages to the most advanced. The Kindergarten system was a fair beginning, but it was too restrictive. Observation and experiment were the means by which truth had to be discovered, and when science was taught simultaneously with other subjects they would find that the intelligence of the pupils was heightened, and that their skill in manipulation, and ability to use their hands, would increase, no slight point when it was remembered that the manufacturing population were educated in these schools. It would, in his opinion, help such bodies as the London School Board, who were anxious for this scientific teaching, if the British Association had a permanent committee to consider the question and give assistance if required.

The Rev. A. Harland referred to the difficulties of teaching natural science in the country school. It was not only necessary, he said, that our teachers should have a thoroughly scientific knowledge, but that the inspectors of the schools should also possess it. So little encouragement had the inspector given that he had even told them in their school to drop such subjects as botany, and to confine their attention pretty much to the three R's. He had, however, an evening with the village children, when he tried to give them some knowledge of chemistry and physiology in order to show them the evils of intemperance, and he thought this was much better than making them commit to memory silly recitations, as was the practice in some Bands of Hope.

Miss Becker (Manchester School Board), after remarking that the question of giving children scientific teaching was only valuable as to the help it would give them in making their way through the world, said she was sorry the science of mechanics was confined to the boy's school because any girl or woman who had to do household work was painfully conscious that she had frequently to move weights, and if she understood the principles of mechanical science it would be far less laborious and less painful—in fact, the principle of the lever was of the utmost consequence in domestic economy. The scrubbing of a floor, and the carrying of a coal-box were mechanical operations which were much better done on scientific principles. Animal physiology had a very close relation to the infant's organisation in its most tender stages, and in the interests of the babies she did think it most important that the common elementary principles of physiology should be known to their mothers.

After some further remarks by Miss Becker, showing the value of a knowledge of science in the commonest duties of every-day life,

Prof. Silvanus Thompson spoke of the advantage of apprenticeship schools, but said that if such schools were established in England it would be by local, rather than Imperial effort, for they succeeded better when they were not fettered by Imperial legislation. Whatever science teaching existed was not merely a scrap, but part of the organic whole, and this was sufficiently elastic to allow of there being special schools, a building school, a school of carpentry, a school for other kinds of technical education, all having their base in the elementary schools; but there should be more community of idea between the lower and the higher scientific training. Miss Becker had affirmed that children seven years old ought to be able to read perfectly if they were scientifically taught, but they were not scientifically taught, nor did he think the difficulty would be removed until they had done away with the abominable irregularities of the detestable English spelling, and reformed the table book.

The Rev. W. Delaney (St. Stanislaus College, Tullamore) said he should like to change the idea that science was merely the handmaid of education, for he believed it was really the best educational weapon, and as a schoolmaster he valued almost infinitesimally the knowledge that boys and girls, and even university men, carried with them into life. Education hitherto had gone too much in grooves, and what they required was a great improvement in scientific teaching, especially in intermediate schools, where it was in a deplorable state. He found that boys who could learn nothing learn science easily, and that when they had learnt science they could learn other things easily. There was an absolute inutility and absurdity in teaching grammar in which boys were taught to know the unknown by the unknown, and he found moreover that whilst Latin and Greek were well known in scientific schools, scholars simply studying the classics often failed in that special study, whereas those who studied science as well as classics passed often at the head of the list.

The President (Mr. Mundella) in summing up the discussion, said he believed that science teaching tended to redeem school life from its drudgery and monotony. In the science schools abroad the interest manifested by the children in a proper object lesson, and the facility with which they acquired knowledge, had very much struck him. The step which, above all others,

was the most necessary in education was to awaken the interest of the children in the subject taught. The children would be taught to think for themselves. Therefore, he had always supported science teaching in schools not only for its great utility, but from a belief that if science teaching was coupled with the ordinary literary teaching of schools, a knowledge of the literary subjects would be more easily acquired. It did not surprise him to hear that there was a good deal in our national education system that needed reform. They had just heard from a successful and accomplished teacher in this town that science could not be taught, because the inspectors themselves discouraged the teaching of it. Young gentlemen fresh from the Universities—some of them very accomplished—were made the inspectors of the whole elementary schools in the country, by a system of patronage and not of selection. They were very highly paid, and they were appointed inspectors because perhaps their fathers or near relatives had rendered a service to some particular political party whichever it might be. But that was altogether a wrong state of matters with reference to education. In London he was now constantly hearing a cry as to whether we are not over-educating the people. Although all present might acquiesce to-day in this discussion, throughout society the cry was, "We are over-educating our people." The real truth was, that people had yet to learn to begin to educate children. They were all very proud of what had been done by the Education Act of 1870, and he should be the last man to undervalue that Act. But as for having an educational system, he declared they had none. To begin with, they should have a Minister of Education who would deal with education solely, and who would know something about his business. Education ought not to be mixed up in the Education Department with vaccination and cattle plague, and other things. It seemed that all the heterogeneous things there was no room for in other departments had been sent to the Education Department. He not only supported science teaching in schools, but he wanted to see it carried to a higher state than the mere teaching of it in schools. Should the British Association visit this town some twenty years hence, they might reasonably expect to find "home-bred" scientific men who would appreciate more highly the Association's labours.

Prof. S. P. Thompson read a paper *On Apprentice Schools in France*.—The problem to be solved was—how to give that technical training and scientific knowledge to artisan children which their occupation demanded, without detaining them so long at their schooling as to give them a distaste for manual labour. There were four solutions of the problem, all of which had been tried, and illustrations of which could be seen in Paris. They were (1) send the children to work in the factory or workshop at an earlier age, making it obligatory all through their apprenticeship that they should have every day a certain number of hours' schooling in a school in the workshop or attached to it. (2) Keep the children at school as long as their education was unfinished, but set up a workshop in the school where they should pass a certain amount of time every day so as to gain at least an aptitude for manual labour. (3) Organise a school and a workshop side by side and co-ordinate the hours given to study with an equal number of hours devoted to systematic manual labour; and (4) send the children half the day to the existing schools, and the other half to work half-time in the workshop or factory. Schools of the first type had existed in France for nearly thirty years, and at the close of 1878 there were no fewer than 237 schools of this character. So far as he was aware, there was only one school of the second type—the Ecole communale d'Apprentis, in the Rne Tournefort, Paris. The peculiarity of this school was that workshop training was being given to lads who had not yet completed a course of elementary education. Of the third type some admirable examples were to be seen in Paris. Some very interesting particulars were given of the progress of the horological school at Besançon. The fourth type or half-time school, which was English in its origin, was rarely to be found in France. Since the old apprenticeship had virtually lapsed, there was nothing to save the young artisan of the rising generation from degenerating into a mere machine, unless a new agency could be practically organised. What was claimed for the apprenticeship school was that its pupils do not possess just a bare minimum of knowledge sufficient to procure them means of subsistence in one narrow department of one restricted industry, but that they possess both manual dexterity and a fair technical knowledge which would enable them not only to earn more and to turn out better work, but also to be less at the mercy of the fluctuation of trade for the means of subsistence. Besides the new apprenticeship being better for real instruction in technical principles, it was also better for practical work in so far as it shortened the needlessly long years of the apprenticeship, and imparted at an earlier age all the manual capacity that apprenticeship in any form could impart. There were not wanting on our horizon signs of significance in the problem of the relation of science to labour. We had really skilled workmen, and no foreign workmen were their equals, but they were only units in a crowd. Take which view they would, technical education, and above all, the technical education of the artisan classes was a *sine quâ non* of the future industrial prosperity of Great Britain. What steps then must be taken to give effect to the new apprenticeship? Two things would determine the success or failure of the school—(1) the obtaining of the right kind of teachers, and (2) the adoption of a system of instruction based upon drawing, which was the language of the manufactures, the handicrafts, the constructive industries of all kinds. It was evident that the first step would be the foundation of a system for training competent teachers. Then there must be a central technical college, for through such an institution alone could community of thought and method of work be obtained. If such a system of technical education as he pointed out was to be instituted, the nation must move towards its accomplishment with a spirit very different from that in which it had viewed technical education during the last quarter of a century. Crisis after crisis had passed, and capitalists and unionist artisans either would not, could not, or dare not confess that the core of all the rottenness was the failure of the old apprenticeship to cope with the requirements of the age and the new social conditions brought about by the fierce rivalries of industry.

AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE

THE twenty-eighth meeting of the American Association for the Advancement of Science was commenced on Wednesday, August 27, at Saratoga Springs, N.Y. After the formal opening in the Town Hall, the proceedings of the first day were mostly concerned with organisation. We give below, in part, the address of the retiring president, Prof. O. C. Marsh, which was delivered on the evening of the 28th, and we hope shortly to offer further intelligence of the scientific work of the meeting.

The new President is Prof. George F. Barker, of Philadelphia; the Vice-president in Section A (comprising Mathematics, Astronomy, Physics, Chemistry, and Mineralogy), Prof. Langley, of Alleghany; and that in Section B (Geology, Zoology, and Botany), Major Powell, of Washington. Prof. Clarke was chairman in Chemistry (sub-Section C), Dr. Morley in Microscopy (sub-Section D) and Dr. D. Wilson in Anthropology (sub-Section E). In addition to the presidential addresses and ordinary work of the sections, we note from the programme that Dr. Edison was to give, on the Saturday evening, an illustrated paper on "The Electro-Chemical Telephone;" while Monday evening was to be devoted in general session to hearing three papers by Professors Chandler, Hall, and Hunt on the mineral waters of Saratoga. There is a goodly list of over 150 papers to be read before the various sections (and it is, by the way, a commendable feature, that the time each would occupy in reading is exactly stated). The following are, briefly, some of the subjects:—In Section A: Experimental determination of the velocity of light (Michelson); Cooling of the sun and the earth (Peirce); Solubility of ozone (Leeds); A general law indicating the location of planets, satellites, or annular rings round their primary (Marsden); Metrology and the progress of science (Barnard); Double stars (Hall); Identity of lines of oxygen with bright solar lines (Draper); Binaural audition (Bell); Conversion of mechanical energy into heat by magneto-electric machines (Barker); Phenomena of heating metal *in vacuo* by means of an electric current (Edison); Influence of light on electric conductivity of metals (Wright). In Section B: Succession of glacial deposits in New England (Upham); Histology of insects (Minot); Conditions to be fulfilled by a theory of life (Minot); Philosophy of the pupation of butterflies (Riley); Consonantal expression of emotion (Blake); Microscopic crystals in the vertebra of the toad (Bolton); The inter-oceanic canal problem (Lull); Bornean orangs (Hornaday); Objects of sex and of odour in flowers (Meehan); Remarkable crinoidal form recently found in Tennessee (Safford); New unpolarisable elec-

trodes for physiological research (Bowditch); Triassic rocks of New Jersey (Cook); Geological action of the acid of humus (Julien); Anatomy of the cat's brain (Wilder); Anthracite coal-fields of Pennsylvania, and their rapid exhaustion (Sheafer); Development of neuration in the wings of insects (Scudder). In sub-Section C: Reduction of carbonic acid by phosphorus at ordinary temperature (Leeds); Deterioration of library bindings (Nichols); Variations in temperature and chemical character of the water of Fresh Pond, Mass. (Nichols); Revision of the atomic weights (Clarke); Results of systematic analysis of air (Morley); Meteorological conditions of beet-root culture (McMurtrie). In sub-Section E: Superstitions of ancient inhabitants of the Mississippi valley relative to rabbits, serpents, owls, &c. (Henderson); Archæological notes from Japan (Morse); Ethnical influences of physical geography (Wilson); The sign language of the North American Indians (Mulbery); Archæology of the Champlain valley (Perkins); Ethnology of the islands of the Indian and Pacific Oceans (Bickmore); Pottery and stone implements of the southern mound-builders (Putnam).

Excursions were arranged to Luzerne, Lake George, Ausable Chasm, Howe's Cave, Montreal, Rutland, Port Henry, and Plattsburgh. On presentation of certificates, members could make free use of the wires of the Western Union Telegraph Company. They could also purchase at nominal rates tickets entitling them to all the privileges of the Congress Spring Park, day or night.

HISTORY AND METHODS OF PALÆONTOLOGICAL DISCOVERY[1]

IN the rapid progress of knowledge, we are constantly brought face to face with the question, What is Life? The answer is not yet, but a thousand earnest seekers after truth seem to be slowly approaching a solution. This question gives a new interest to every department of science that relates to life in any form, and the history of life offers a most suggestive field for research. One line of investigation lies through embryology, and here the advance is most encouraging. Another promising path leads back through the life history of the globe, and in this direction we may hope for increasing light, as a reward for patient work.

The plants and animals now living on the earth interest alike the savage and the savant, and hence have been carefully observed in every age of human history. The life of the remote past, however, is preserved only in scanty records, buried in the earth, and therefore readily escapes attention. For these reasons, the study of ancient life is one of the latest of modern sciences, and among the most difficult. In view of the great advances which this department of knowledge has made within the last decade, especially in this country, I have thought it fitting to the present occasion to review briefly its development, and have chosen for my subject this evening, THE HISTORY AND METHODS OF PALÆONTOLOGICAL DISCOVERY.

In the short time now at my command, I can only attempt to present a rapid sketch of the principal steps in the progress of this science. The literature of the subject, especially in connection with the discussions it provoked, is voluminous, and an outline of the history itself must suffice for my present purpose.

In looking over the records of palæontology, its history may conveniently be divided into four periods, well marked by prominent features, but, like all stages of intellectual growth, without definite boundaries.

The first period, dating back to the time when men first noticed fossil remains in the rocks, and queried as to their nature, is of special interest in this connection. The most prominent characteristic of this period was a long and bitter contest as to the *nature of fossil remains*. Were they mere "sports of Nature," or had they once been endowed with life? Simple as this problem now seems, centuries passed before the wise men of that time were agreed upon its solution.

Sea shells in the solid rocks on the tops of mountains early attracted the attention of the ancients, and the learned men among them seem to have appreciated in some instances their true character, and given rational explanations of their presence.

The philosopher Zenophanes, of Colophon, who lived about 500 B.C., mentions the remains of fishes and other animals in the stone quarries near Syracuse; the impression of an anchovy in the rock of Paros, and various marine fossils at other places. His conclusion from these facts was, that the surface of the earth had once been in a soft condition at the bottom of the sea; and thus the objects mentioned were entombed. Herodotus, half a century later, speaks of marine shells on the hills of Egypt, and over the Libyan desert, and he inferred therefrom that the sea had once covered that whole region. Empedocles, of Agrigentum (450 B.C.), believed that the many hippopotamus bones found in Sicily were remains of human giants, in comparison with which the present race were as children. Here, he thought, was a battle-field between the gods and the Titans, and the bones belonged to the slain. Pythagoras (582 B.C.) had already anticipated one conclusion of modern geology, if the following statement, attributed to him by Ovid, was his own:[1]

> Vidi ego quod fuerat solidissima tellus,
> Esse fretum: vidi factas ex æquore terras:
> Et procul a pelago conchæ jacuere marinæ.

Aristotle (384-322 B.C.) was not only aware of the existence of fossils in the rocks, but has also placed on record sagacious views as to the changes in the earth's surface necessary to account for them. In the second book of his meteorics, he says: "The changes of the earth are so slow in comparison to the duration of our lives, that they are overlooked; and the migrations of people after great catastrophes and their removal to other regions, cause the event to be forgotten." Again, in the same work, he says: "As time never fails, and the universe is eternal, neither the Tànais, nor the Nile, can have flowed for ever. The places where they rise were once dry, and there is a limit to their operations: but there is none to time. So of all other rivers; they spring up and they perish; and the sea also continually deserts some lands and invades others. The same tracts, therefore, of the earth are not, some always sea, and others always continents, but everything changes in the course of time."

Aristotle's views on the subject of spontaneous generation were less sound, and his doctrines on this subject exerted a powerful influence for the succeeding twenty centuries. In the long discussion that followed concerning the nature of fossil remains, Aristotle's views were paramount. He believed that animals could originate from moist earth or the slime of rivers, and this seemed to the people of that period a much simpler way of accounting for the remains of animals in the rocks than the marvellous changes of sea and land otherwise required to explain their presence. Aristotle's opinion was in accordance with the Biblical account of the creation of man out of the dust of the earth, and hence more readily obtained credence.

Theophrastus, a pupil of Aristotle, alludes to fossil fishes found near Heraclea in Pontus, and in Paphlagonia, and says: "They were either developed from fish spawn left behind in the earth, or gone astray from rivers or the sea into cavities of the earth, where they had become petrified." In treating of fossil ivory and bones, the same writer supposed them to be produced by a certain plastic virtue latent in the earth. To this same cause, as we shall see, many later authors attributed the origin of all fossil remains.

Previous to this, Anaximander, the Miletian philosopher, who was born about 610 years before Christ, had expressed essentially the same view. According to both Plutarch and Censorinus, Anaximander taught that fishes, or animals very like fishes, sprang from heated water and earth, and from these animals came the human race; a statement which can hardly be considered as anticipating the modern idea of evolution, as some authors have imagined.

The Romans added but little to the knowledge possessed by the Greeks in regard to fossil remains. Pliny (23-79 A.D.), however, seems to have examined such objects with interest, and in his renowned work on Natural History gave names to several forms. He doubtless borrowed largely from Theophrastus, who wrote about three hundred years before. Among the objects named by Pliny were, "*Bucardia*, like to an ox's heart;" "*Brontia*, resembling the head of a tortoise, supposed to fall in thunderstorms;" "*Glossoptra*, similar to a human tongue which does not grow in the earth, but falls from heaven while the moon is

[1] An Address, delivered before the American Association for the Advancement of Science, at Saratoga, N.Y., August 28, 1879, by Prof. O. C. Marsh, President.

eclipsed;" "the *Horn of Ammon*, possessing, with a golden colour, the figure of a ram's horn;" *Ceraunia* and *Ombria*, supposed to be thunderbolts; *Ostracites*, resembling the oyster shell; *Spongites*, having the form of sponge; *Phycites*, resembling sea-weed or rushes. He also mentions stones resembling the teeth of hippopotamus; and says that Theophrastus speaks of fossil ivory, both black and white, of bones born in the earth, and of stones bearing the figure of bones.

Tertullian (160 A.D.) mentions instances of the remains of sea animals on the mountains, far from the sea, but uses them as a proof of the general deluge recorded in Scripture.

During the next thirteen or fourteen centuries, fossil remains of animals and plants seem to have attracted so little attention, that few references are made to them by the writers of this period. During these ages of darkness, all departments of knowledge suffered alike, and feeble repetitions of ideas derived from the ancients seem to have been about the only contributions of that period to Natural Science.

Albert the Great (1205–1280 A.D.), the most learned man of his time, mentions that a branch of a tree was found, on which was a bird's nest containing birds, the whole being solid stone. He accounted for this strange phenomenon by the *vis formativa* of Aristotle, an occult force, which, according to the prevalent notions of the time, was capable of forming most of the extraordinary objects discovered in the earth.

Alexander *ab Alexandro*, of Naples, states that he saw, in the mountains of Calabria, a considerable distance from the sea, a variegated hard marble, in which many sea shells but little changed were heaped, forming one mass with the marble.

With the beginning of the sixteenth century, a great impetus was given to the investigation of organic fossils, especially in Italy, where this study really began. The discovery of fossil shells, which abound in this region, now attracted great attention, and a fierce discussion soon arose as to the true nature of these and other remains. The ideas of Aristotle in regard to spontaneous generation, and especially his view of the hidden forces of the earth, which he claimed had power to produce such remains, now for the first time were seriously questioned, although it was not till nearly two centuries later that these doctrines lost their dominant influence.

Leonardo da Vinci, the renowned painter and philosopher, who was born in 1452, strongly opposed the commonly accepted opinions as to the origin of organised fossils. He claimed that the fossil shells under discussion were what they seemed, and had once lived at the bottom of the sea. "You tell me," he says, "that Nature and the influence of the stars have formed these shells in the mountains; then show me a place in the mountains where the stars at the present day make shelly forms of different ages, and of different species in the same place." Again, he says, "In what manner can such a cause account for the petrifactions in the same place of various leaves, sea-weeds, and marine crabs?"

In 1517, excavations in the vicinity of Verona brought to light many curious petrifactions, which led to much speculation as to their nature and origin. Among the various authors who wrote on this subject was Fracastoro, who declared that the fossils once belonged to living animals, which had lived and multiplied where found. He ridiculed the prevailing ideas that the plastic force of the ancients could fashion stones into organic forms. Some writers claimed that these shells had been left by Noah's flood, but to this idea Fracastoro offered a mass of evidence which would now seem conclusive, but which then only aroused bitter hostility. That inundation, he said, was too transient; it consisted mainly of fresh water; and if it had transported shells to great distances, must have scattered them over the surface, not buried them in the interior of mountains.

Conrad Gesner (1516—1565), whose history of animals has been considered the basis of modern zoology, published at Zurich in 1565 a small but important work entitled "De rerum Fossilium, Lapidum, et Gemmarum figuris." It contained a catalogue of the collection of fossils made by John Kentmann. This is the oldest catalogue of fossils with which I am acquainted.

George Agricola (1494—1555) was, according to Cuvier, the first mineralogist who appeared after the revival of learning in Europe. In his great work, "De Re Metalica," published in 1546, he mentions various fossil remains, and says they were produced by a certain *materia pinguis*, or fatty matter, set in fermentation by heat. Some years later Bauhin published a descriptive catalogue of the fossils he had collected in the neighbourhood of Boll, in Würtemberg.[1]

Andrew Mattioli, a distinguished botanist, adopted Agricola's notion as to the origin of organized fossils, but admitted that shells and bones might be turned into stone by being permeated by a "lapidifying juice." Falloppio, the eminent professor of anatomy at Padua, believed that fossil shells were generated by fermentation where they were found; and that the tusks of elephants, dug up near Apulia, were merely earthy concretions. Mercati, in 1574, published figures of the fossil shells preserved in the Museum of the Vatican, but expressed the opinion that they were only stones, that owed their peculiar shapes to the heavenly bodies. Olivi, of Cremona, described the fossils in the Museum at Verona, and considered them all "sports of nature."

Palissy, a French author, in 1580, opposed these views, and is said to have been the first to assert in Paris that fossil shells and fishes had once belonged to marine animals. Fabio Colonna appears to have first pointed out that some of the fossil shells found in Italy were marine, and some terrestrial.

Another peculiar theory discussed in the sixteenth century deserves mention. This was the vegetation theory, especially advocated by Tournefort and Camerarius, both eminent as botanists. These writers believed that the seeds of minerals and fossils were diffused throughout the sea and the earth, and were developed into their peculiar forms by the regular increment of their particles, similar to the formation of crystals. "How could the *Cornu Ammonis*," Tournefort asked, "which is constantly in the figure of a volute, be formed without a seed containing the same structure in the small, as in the larger forms? Who moulded it so artfully, and where are the moulds?" The stalactites which formed in caverns in various parts of the world were also supposed to be proofs of this vegetative growth.

Still another theory has been held at various times, and is not yet entirely forgotten, namely: that the Creator made fossil animals and plants just as they are found in the rocks, in pursuance of a plan beyond our comprehension. This theory has never prevailed among those familiar with scientific facts, and hence needs here no further consideration.

An interest in fossil remains arose in England later than on the Continent; but when attention was directed to them, the first opinions as to their origin were not less fanciful and erroneous than those to which we have already referred. Dr. Plot, in his "Natural History of Oxfordshire," published in 1677, considered the origin of fossil shells and fishes to be due to a "plastic virtue, latent in the earth," as Theophrastus had suggested long before. Lhwyd, in his "Lithophylacii Britannici Ichnographia," published at Oxford in 1699, gives a catalogue of English fossils contained in the Ashmolean Museum. He opposed the *vis plastica* theory, and expressed the opinion that the spawn of fishes and other marine animals had been raised with the vapours from the sea, conveyed inland by clouds, and deposited by rain, had permeated into the interior of the earth, and thus produced the fossil remains we find in the rocks. About this time several important works were published in England by Dr. Martin Lister, which did much to infuse a true knowledge of fossil remains. He gave figures of recent shells side by side with some of the fossil forms, so that the resemblance became at once apparent. The fossil species of shells he called "turbinated and bivalve stones," and adds, "either these were terriginous, or if otherwise, the animals which they so exactly represent have become extinct."

During the seventeenth century there was a considerable advance in the study of fossil remains. The discussions in regard to the nature and origin of these objects had called attention to them, and many collections were now made, especially in Italy, and also in Germany, where a strong interest in this subject had been aroused. Catalogues of these collections were not unfrequently published, and some of them were illustrated with such accurate figures, that many of the species can now be readily recognized. In this century, too, an important step in advance was made by the collection and description of fossils from particular localities and regions, in distinction from general collections of curiosities.

Casper Schwenkfeld, in 1600, published a catalogue of the

[1] "Historia novi et admirabilis Fontis Balneique Bollensis, in Ducata Wirtembergico." Moulbeillard, 1598.

fossils discovered in Silesia; in 1622, a detailed description of the renowned Museum of Calceolarius, of Verona, appeared; and in 1642, a catalogue of Besler's collection; Warmius's catalogue was published in 1652; Spener's in 1663; and Septala's in 1666. A description of the Museum of the King of Denmark was issued in 1669; Cottorp's catalogue in 1674, and that of the renowned Kirscher in 1678. Dr. Grew gave an account in 1687 of the specimens in the Museum of Gresham's College in England; and in 1695, Petiver of London published a catalogue of his very extensive collection. A catalogue by Fred. Lauchmund, on the fossils of Hildesheim, appeared in 1669, and the fossils of Switzerland were described by John Jacob Wagner in 1689. Among similar works were the dissertations of Gyer at Frankfort, and Albertus at Leipsic.

Steno, a Dane, who had been professor of Anatomy at Padua, published, in 1669, one of the most important works of this period.[1] He entered earnestly into the controversy as to the origin of fossil remains, and by dissecting a shark from the Mediterranean, proved that its teeth were identical with some found fossil in Tuscany. He also compared the fossil shells found in Italy with existing species, and pointed out their resemblance. In the same work, Steno expressed some very important views in regard to the different kinds of strata, and their origin, and first placed on record the important fact that the oldest rocks contain no fossils.

Scilla, the Sicilian painter, published in 1670 a work on the fossils of Calabria, well illustrated. He is very severe against those who doubted the organic origin of fossils, but is inclined to consider them relics of the Mosaic deluge.

Another instance of the power of the *lusus naturæ* theory, even at the close of the seventeenth century, deserves mention. In the year 1696, the skeleton of a fossil elephant was dug up at Tonna, near Gotha, in Germany, and was described by William Ernest Tentzel, a teacher in the Gotha Gymnasium. He declared the bones to be the remains of an animal that had lived long before. The Medical Faculty in Gotha, however, considered the subject, and decided officially that this specimen was only a freak of nature.

Beside the authors I have mentioned, there were many others who wrote about fossil remains before the close of the seventeenth century, and took part in the general discussion as to their nature and origin. During the progress of this controversy the most fantastic theories were broached, and stoutly defended, and although refuted from time to time by a few clear-headed men, continually sprang up anew, in the same or modified forms. The influence of Aristotle's views of equivocal generation, and especially the scholastic tendency to disputation, so prevalent during the middle ages, had contributed largely to the retardation of progress, and yet a real advance in knowledge had been made. The long contest in regard to the nature of fossil remains was essentially over, for the more intelligent opinion at the time now acknowledged that these objects were not mere "sports of nature," but had once been endowed with life. At this point, therefore, the first period in the history of palæontology, as I have indicated it, may appropriately end.

It is true that later still, the old exploded errors about the plastic force and fermentation were from time to time revived, as they have been almost to the present day; but learned men, with few exceptions, no longer seriously questioned that fossils were real organisms, as the ancients had once believed. The many collections of fossils that had been brought together, and the illustrated works that had been published about them, were a foundation for greater progress, and, with the eighteenth century, the second period in the history of palæontology began.

The main characteristic of this period was the general belief that *fossil remains were deposited by the Mosaic deluge*. We have seen that this view had already been advanced, but it was not till the beginning of the eighteenth century that it became the prevailing view. This doctrine was strongly opposed by some courageous men, and the discussion on the subject soon became even more bitter than the previous one, as to the nature of fossils.

In this diluvial discussion theologians and laymen alike took part. For nearly a century the former had it all their own way, for the general public, then as now, believed what they were taught. Noah's flood was thought to have been universal, and was the only general catastrophe of which the people of that day had any knowledge or conception.

[1] "De Solido intra Solidum naturaliter Contento."

The scholars among them were of course familiar with the accounts of Deucalion and his ark, in a previous deluge, as we are to-day with similar traditions held by various races of men. The firm belief that the earth and all it contains was created in six days; that all life on the globe was destroyed by the deluge excepting alone what Noah saved; and that the earth and its inhabitants were to be destroyed by fire, was the foundation on which all knowledge of the earth was based. With such fixed opinions, the fossil remains of animals and plants were naturally regarded as relics left by the flood described in Holy Writ. The dominant nature of this belief is seen in nearly all the literature in regard to fossils published at this time, and some of the works which then appeared have become famous on this account.

In 1710, David Büttner published a volume entitled "Rudera Diluvii Testes." He strongly opposed Lhwyd's explanation of the origin of fossils, and referred these objects directly to the flood. The most renowned work, however, of this time, was published at Zurich, in 1726, by Scheuchzer, a physician and naturalist, and professor in the University of Altorf. It bore the title "Homo Diluvii Testis." The specimen upon which this work was based was found at Oeningen, and was regarded as the skeleton of a child destroyed by the deluge. The author recognised in this remarkable fossil, not merely the skeleton, but also portions of the muscles, the liver, and the brain. The same author was fortunate enough to discover, subsequently, near Altorf, two fossil vertebræ, which he at once referred to that "accursed race destroyed by the flood!" These, also, he carefully described and figured in his "Physica Sacra," published at Ulm in 1731. Engravings of both were subsequently given in the "Copper-Bible." Cuvier afterwards examined these interesting relics and pronounced the skeleton of the supposed child to be the remains of a gigantic salamander, and the two vertebræ to be those of an ichthyosaurus!

Another famous book appeared in Germany in the same year in which Scheuchzer's first volume was published. The author was John Bartholomew Adam Beringer, professor at the University of Würtzburg, and his great work[1] indirectly had an important influence upon the investigation of fossil remains. The history of the work is instructive, if only as an indication of the state of knowledge at that date. Prof. Beringer, in accordance with views of his time, had taught his pupils that fossil remains, or "figured stones," as they were called, were mere "sports of nature." Some of his fun-loving students reasoned among themselves, "if nature can make figured stones in sport, why can not we?" Accordingly, from the soft limestone in the neighbouring hills, they carved out figures of marvellous and fantastic forms, and buried them at the localities where the learned professor was accustomed to dig for his fossil treasures. His delight at the discovery of these strange forms encouraged further production, and taxed the ingenuity of these youthful imitators of Nature's secret processes. At last Beringer had a large and unique collection of forms, new to him, and to science, which he determined to publish to the world. After long and patient study, his work appeared, in Latin, dedicated to the reigning prince of the country, and illustrated with twenty-one folio plates. Soon after the book was published, the deception practised upon the credulous professor became known; and in place of the glory he expected from his great undertaking, he received only ridicule and disgrace. He at once endeavoured to repurchase and destroy the volumes already issued, and succeeded so far that few copies of the first edition remain. His small fortune, which had been seriously impaired in bringing out his grand work, was exhausted in the effort to regain what was already issued, as the price rapidly advanced in proportion as fewer copies remained; and, mortified at the failure of his life's work, he died in poverty. It is said that some of his family, dissatisfied with the misfortune brought upon them by this disgrace and the loss of their patrimony, used a remaining copy for the production of a second edition, which met with a large sale, sufficient to repair the previous loss, and restore the family fortune. This work of Beringer's, in the end, exerted an excellent influence upon the dawning science of fossil remains. Observers became more cautious in announcing supposed discoveries, and careful study of natural objects gradually replaced vague hypotheses.

The above works, however, are hardly fair examples of the literature on fossils during this part of the eighteenth century. Scheuchzer had previously published his well-known "Com-

[1] "Lithographia Wirceburgensis, ducentis lapidum figuratorum, a potiori, insectiformium, prodigiosis imaginibus exornata." Wirceburgi, 1726. Edit. II. Francofurti et Lipsiæ. 1767.

plaint and Vindication of the Fishes," illustrated with good plates. Moro, in his work on "Marine Bodies which are found in the Mountains," 1740, showed the effects of volcanic action in elevating strata, and causing faults. Vallisneri had studied with care the marine deposits of Italy. Donati, in 1750, had investigated the Adriatic, and ascertained by soundings that shells and corals were being imbedded in the deposits there, just as they were found in the rocks.

John Gesner's dissertation, "De Petrificatis," published at Leyden in 1758, was a valuable contribution to the science. He enumerated the various kinds of fossils, and the different conditions in which they are found petrified, and stated that some of them, like those at Oeningen, resembled the shells, fishes, and plants of the neighbouring region, while others, such as Ammonites and Belemnites, were either unknown species, or those found only in distant seas. He discusses the structure of the earth at length, and speculates as to the causes of changes in sea and land. He estimates that, at the observed rate of recession of the ocean, to allow the Apennines, whose summits are filled with marine shells, to reach their present height, would have taken about eighty thousand years, a period more than "ten times greater than the age of the universe." He accordingly refers the change to the direct command of the Deity, as related by Moses, that, "The waters should be gathered together in one place, and the dry land appear."

Voltaire (1694-1778) discussed geological questions and the nature of fossils in several of his works, but his published opinions are far from consistent. He ridiculed effectively and justly the cosmogonists of his day, and showed, also, that he knew the true nature of organic remains. Finding, however, that theologians used these objects to confirm the Scriptural account of the deluge, he changed his views, and accounted for fossil shells found in the Alps, by suggesting that they were Eastern species, dropped by the pilgrims on their return from the Holy Land!

Buffon, in 1749, published his important work on Natural History, and included in it his "Theory of the Earth," in which he discussed, with much ability, many points in geology. Soon after the book was published he received an official letter from the Faculty of Theology in Paris, stating that fourteen propositions in his works were reprehensible, and contrary to the creed of the Church. The first objectionable proposition was as follows: "The waters of the sea have produced the mountains and valleys of the land,—the waters of the heavens reducing all to a level, will at last deliver the whole land over to the sea, and the sea successively prevailing over the land, will leave dry new continents like those we inhabit."

Buffon was politely invited by the college to recant, and having no particular desire to be a martyr to science, submitted the following declaration, which he was required to publish in his next work: "I declare that I had no intention to contradict the text of Scripture; that I believe most firmly all therein related about the creation, both as to order of time and matter of fact; and I abandon everything in my book respecting the formation of the earth, and, generally, all which may be contrary to the narration of Moses."

This single instance will suffice to indicate one great obstacle to the advancement of science, even up to the middle of the eighteenth century.

Another important work appeared in France about this time, Bourguet's "Traité des Petrifactions," published in 1758, which is well illustrated with faithful plates. In England, a discourse on earthquakes, by Dr. Robert Hooke, was published in 1705. This author held some views in advance of his time, and maintained that figured stones were "really the several bodies they represent or the mouldings of them petrified, and not, as some have imagined, a *lusus naturæ*, sporting herself in the needless formation of useless things." He anticipates one important conclusion from fossils, when he states that "though it must be very difficult to read them and to raise a chronology out of them, and to state the intervals of time wherein such or such catastrophes and mutations have happened, yet it is not impossible." He also states that fossil turtles and such large Ammonites as are found in Portland, seem to have been the productions of hotter countries, and hence it is necessary to suppose that England once lay under the sea within the torrid zone. He seems to have suspected that some of the fossils of England belonged to extinct species, but thought possibly they might be found living in the bottom of distant oceans.

Dr. Woodward's "Natural History of the Fossils of England" appeared in 1729. This work was based on a systematic collection of fossils which he had brought together, and which he subsequently bequeathed to the University of Cambridge, where it is still preserved, with his arrangement carefully retained. The descriptive part of this work is interesting, but his conclusions are made to coincide strictly with the Scriptural account of the creation and deluge. He had previously stated, in another work, that he believed, "the whole terrestrial globe to have been taken to pieces and dissolved at the flood, and the strata to have settled down from this promiscuous mass." In support of this view, he stated that, "Marine bodies are lodged in the strata according to the order of their gravity, the heavier shells in stones, the lighter in chalk, and so of the rest."[1]

The most important work on fossils published in Germany at this time, was that of George Wolfgang Knorr, which was continued after his death by Walch. This work consisted of four folio volumes, with many plates, and was printed at Nuremberg, 1755-73. A large number of fossils were accurately figured and described, and the work is one of permanent value.[2] A French translation of this work appeared in 1767-78. Burton's "Oryctographie de Bruxelles," 1784, contains figures and descriptions of fossils found in Belgium.

Abraham Gottlieb Werner (1750–1817), Professor of Mineralogy at Freyberg, did much to advance the science of geology, and indirectly, that of fossils. He first indicated the relations of the main formations to each other, and, according to his pupil, Prof. Jameson, first made the highly important observation "that different formations can be discriminated by the petrifactions they contain." Moreover, "that the petrifactions contained in the oldest rocks are very different from any of the species of the present time; that the newer the formation, the more do the remains approach in form to the organic beings of the present creation." Unfortunately, Werner published little, and his doctrines were mainly disseminated by his enthusiastic pupils.

The great contest between the Vulcanists and the Neptunists started at this time, mainly through Werner, whose doctrines led to the controversy. The comparative merits of fire and water, as agencies in the formation of certain rocks, were discussed with a heat and acrimony characteristic of the subject and the time. Werner believed in the aqueous theory, while the igneous theory was especially advocated by Hutton of Edinburgh and his illustrator, Playfair. This discussion resulted in the advancement of descriptive geology, but the study of fossils gained little thereby.

The "Protogæa" of Leibnitz, the great mathematician, published in 1749, about thirty years after his death, was a work of much merit. This author supposed that the earth had gradually cooled from a state of igneous fusion, and was subsequently covered with water. The subsidence of the lower part of the earth; the deposits of sedimentary strata from inundations, and their induration, as well as other changes, followed. All this, he supposed to have been accomplished in a period of six natural days. In the same work Leibnitz shows that he had examined fossils with considerable care.

Linnæus (1707–1778), the famous Swedish botanist, and the founder of the modern system of nomenclature in Natural History, confined his attention almost entirely to the living forms. Although he was familiar with the literature of fossil remains, and had collected them himself, he did not include them in his system of plants and animals, but kept them separate, with the minerals; hence he did little directly to advance this branch of science.

During the last quarter of the eighteenth century, the belief that fossil remains were deposited by the deluge sensibly declined, and the dawn of a new era gradually appeared. Let us pause for a moment here and see what real progress had been made; what foundation had been laid on which to establish a science of fossil remains.

The true nature of these objects had now been clearly determined. They were the remains of animals and plants. Most of them certainly were not the relics of the Mosaic deluge, but had been deposited long before, part in fresh water and part in the sea. Some indicated a mild climate, and some the tropics. That any of these were extinct species, was as yet only suspected. Large collections of fossils had now been made, and valuable catalogues, well illustrated, had been pub-

[1] "Essay towards a Natural History of the Earth." 1695.

[2] "Lapides ex celeberr. viror. sententia diluvii universalis testes, quos in ordines ac species distribuit, suis caloribus expremit, etc." 272 Tab. 1755-73.

lished. Something was known, too, of the geological position of fossils. Steno, long before, had observed that the lowest rocks were without life. Lehmann had shown that above these primitive rocks, and derived from them, were the secondary strata, full of the records of life, and above these were alluvial deposits, which he referred to local floods and the deluge of Noah. Rouelle, Fuchsel, and Odoardi had shed new light on this subject. Werner had distinguished the transition rocks, containing fossil remains, between the primitive and the secondary, while everything above the chalk he grouped together as "The overflowed land." Werner, as we have seen, had done more than this, if we give him the credit his pupils claim for him. He had found that the formations he examined contained each its own peculiar fossils, and from the older to the newer there was a gradual approach to recent forms. William Smith had worked out the same thing in England, and should equally divide the honour of this important discovery.

The greatest advance, however, up to this time was that men now preferred to *observe* rather than to *believe*, and facts were held in greater esteem than vague speculations. With this preparation for future progress, the second period in the history of palæontology, as I have divided it, may appropriately be considered at an end.

Thus far I have said nothing in regard to one branch of my subject, the *methods* of palæontological research, for up to this time, of method there was none. We have seen that those of the ancients who noticed marine shells in the solid rock, called them such, and concluded that they had been left there by the sea. The discovery of fossils led directly to theories of how the earth was formed. Here the progress was slow. Subterranean spirits were supposed to guard faithfully the mysteries of the earth, while above the earth, Authority guarded with still greater power the secrets men in advance of their age sought to know. The dominant idea of the first sixteen centuries of the present era was, that the universe was made for Man. This was the great obstacle to the correct determination of the position of the earth in the universe, and later, of the age of the earth. The contest of astronomy against authority was long and severe, but the victory was at last with science. The contest of geology against the same power followed, and continued almost to our day. The result is still the same. In the early stages of this contest, there was no strife, for science was benumbed by the embrace of superstition and creed, and little could be done till that was cast off. In a superstitious age, when every natural event is referred to a supernatural cause, science cannot live; and often as the sacred fire may be kindled by courageous far-seeing souls, will it be quenched by the dense mist of ignorance around it. Scarcely less fatal to the growth of science is the age of Authority, as the past proves too well. With freedom of thought, came definite knowledge, and certain progress;—but two thousand years was long to wait.

With the opening of the present century, began a new era in Palæontology, which we may here distinguish as the third period in its history. This branch of knowledge became now a science. Method replaced disorder, and systematic study superseded casual observation. For the next half century the advance was continuous and rapid. One characteristic of this period was, *the accurate determination of fossils by comparison with living forms*. This will separate it from the two former epochs. Another distinctive feature of this period was the general belief that *every species, recent and extinct, was a separate creation*.

At the very beginning of the epoch we are now to consider, three names stand out in bold relief: Cuvier, Lamarck, and William Smith. To these men the science of palæontology owes its origin. Cuvier and Lamarck, in France, had all the power which great talent, education, and station could give; William Smith, an English surveyor, was without culture or influence. The last years of the eighteenth century had been spent by each of these men in preparation for his chosen work, and the results were now given to the world. Cuvier laid the foundation of the palæontology of Vertebrate animals; Lamarck, of the Invertebrates; and Smith established the principles of Stratigraphical Palæontology. The investigator of fossils to-day seldom needs to consult earlier authors of the science.

George Cuvier (1769-1832), the most famous naturalist of his time, was led to the study of extinct animals by ascertaining that the remains of fossil elephants he examined were extinct species. "This idea," he says later, "which I announced to the Institute in the month of January 1796, opened to me views entirely new respecting the theory of the earth, and determined me to devote myself to the long researches and to the assiduous labours which have now occupied me for twenty-five years."[1]

It is interesting to note here that in this first investigation of fossil vertebrates, Cuvier employed the same method that gave him such important results in his later researches. Remains of elephants had been known to Europe for centuries, and many authors, from Pliny down to the contemporaries of Cuvier, had written about them. Some had regarded the bones as those of human giants, and those who recognised what they were considered them remains of the elephants imported by Hannibal or the Romans. Cuvier, however, compared the fossils directly with the bones of existing elephants, and proved them to be distinct. The fact that these remains belonged to extinct species was of great importance. In the case of fossil shells, it was difficult to say that any particular form was not living in a distant ocean; but the two species of existing elephants, the Indian and the African, were well known, and there was hardly a possibility that another living one would be found.

It is important to bear in mind, too, that Cuvier's preparations for the study of the remains of animals was far in advance of any of his predecessors. He had devoted himself for years to careful dissections in the various classes of the animal kingdom, and was really the founder of comparative anatomy, as we now understand it. Cuvier investigated the different groups of the whole kingdom with care, and proposed a new classification founded on the plan of structure, which in its main features is the one in use to-day. The first volume of his Comparative Anatomy appeared in 1800, and the work was completed in five volumes in 1805.

Previous to Cuvier, the only general catalogue of animals was contained in Linnæus' "Systema Naturæ." In this work, as we have seen, fossil remains were placed with the minerals, not in their appropriate places among the animals and plants. Cuvier enriched the animal kingdom by the introduction of fossil forms among the living, bringing all together into one comprehensive system. His great work, "Le Règne Animal," appeared in four volumes in 1817, and with its two subsequent editions remains the foundation of modern zoology. Cuvier's classic work on vertebrate fossils—"Recherches sur les Ossemens Fossiles," in four volumes, appeared in 1812-13. Of this work, it is but just to say that it could only have been written by a man of genius, profound knowledge, the greatest industry, and with the most favourable opportunities.

The introduction to this work was the famous "Discourse on the Revolutions of the Surface of the Globe," which has perhaps been as widely read as any other scientific essay. The discovery of fossil bones in the gypsum quarries of Paris, by the workmen, who considered them human remains; the careful study of these relics by Cuvier, and his restorations from them of strange beasts that had lived long before, is a story with which you are all familiar. Cuvier was the first to prove that the earth had been inhabited by a succession of different series of animals, and he believed that those of each period were peculiar to the age in which they lived.

In looking over his work after a lapse of three-quarters of a century, we can now see that Cuvier was wrong on some important points, and failed to realise the direction in which science was rapidly tending. With all his knowledge of the earth, he could not free himself from tradition, and believed in the universality and power of the Mosaic deluge. Again, he refused to admit the evidence brought forward by his distinguished colleagues against the permanence of species, and used all his great influence to crush out the doctrine of evolution, then first proposed. Cuvier's definition of a species, the dominant one for half a century, was as follows: "A species comprehends all the individuals which descend from each other, or from a common parentage, and those which resemble them as much as they do each other."

The law of "Correlation of Structures," as laid down by Cuvier, has been more widely accepted than almost any thing else that bears his name; and yet, although founded in truth, and useful within certain limits, it would certainly lead to serious error if applied widely in the way he proposed.

In his discourse, he sums this law as follows: "A claw, a shoulder blade, a condyle, a leg or arm bone, or any other bone

[1] "Ossemens fossiles." Second Edition, vol. i. p. 178.

separately considered, enables us to discover the description of teeth to which they have belonged; so also reciprocally we may determine the form of the other bones from the teeth. Thus, commencing our investigation by a careful survey of any one bone by itself, a person who is sufficiently master of the laws of organic structure, may, as it were, reconstruct the whole animal to which that bone had belonged."

We know to-day that unknown extinct animals cannot be restored from a single tooth or claw, unless they are very similar to forms already known. Had Cuvier himself applied his methods to many forms from the early tertiary or older formations, he would have failed. If, for instance, he had had before him the disconnected fragments of an eocene tillodont, he would undoubtedly have referred a molar tooth to one of his pachyderms; an incisor tooth to a rodent; and a claw bone to a carnivore. The tooth of a hesperornis would have given him no possible hint of the rest of the skeleton, nor its swimming feet the slightest clue to the ostrich-like sternum or skull. And yet, the earnest belief in his own methods led Cuvier to some of his most important discoveries.

Jean Lamarck (1744-1829), the philosopher and naturalist, a colleague of Cuvier, was a learned botanist before he became a zoologist. His researches on the invertebrate fossils of the Paris Basin, although less striking, were not less important than those of Cuvier on the vertebrates; while the conclusions he derived from them form the basis of modern biology. Lamarck's method of investigation was the same, essentially, as that used by Cuvier, namely: a direct comparison of fossils with living forms. In this way, he soon ascertained that the fossil shells imbedded in the strata beneath Paris were, many of them, extinct species, and those of different strata differed from each other. His first memoir on this subject appeared in 1802,[1] and, with his later works, effected a revolution in conchology. His "System of Invertebrate Animals" appeared the year before, and his famous "Philosophie zoologique," in 1809. In these two works, Lamarck first announced the principles of evolution. In the first volume of his "Natural History of Invertebrate Animals,"[2] he gave his theory in detail; and to-day one can only read with astonishment his far-reaching anticipations of modern science. These views were strongly supported by Geoffroy Saint-Hilaire, but bitterly opposed by Cuvier; and their great contest on this subject is well known.

In looking back from this point of view, the philosophical breadth of Lamarck's conclusions, in comparison with those of Cuvier, is clearly evident. The invertebrates on which Lamarck worked offered less striking evidence of change than the various animals investigated by Cuvier; yet they lead Lamarck directly to evolution, while Cuvier ignored what was before him on this point, and rejected the proof offered by others. Both pursued the same methods, and had an abundance of material on which to work, yet the facts observed induced Cuvier to believe in catastrophes; and Lamarck, in the uniform course of nature. Cuvier declared species to be permanent; Lamarck, that they were descended from others. Both men stand in the first rank in science; but Lamarck was the prophetic genius, half a century in advance of his time.

(*To be continued.*)

FRENCH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE

THE French Association for the Progress of Science has taken a bold step and decided that its session for 1881 will take place in Algiers. To avoid the numerous inconveniences of the strong heat which prevails all over Algeria in the month of August, it has been decided that the meeting should be held in April, during the Easter recess.

This happy result of the deliberations must be attributed to the personal exertions of M. Albert Grévy, the brother of the President of the French Republic, who holds the post of Civil Governor-General of Algeria.

It is supposed that the new scientific establishment whose formation has been decreed this year, will be formally inaugurated on this occasion, and a scientific movement of some importance will take place in the colony.

The *Akhbar* announced a few days back that a geographical society is being organised in Algiers.

[1] "Mémoire sur les Fossiles des Environs de Paris." 1802-6.

[2] "Histoire naturelle des Animaux sans Vertèbres." 7 vols. Paris, 1815-1822. Second Edition. 11 vols. 1835-1845.

In the meantime a number of representatives headed by Algerian senators and deputies will make a tour of exploration during the month of October. They will start at the end of September, as we announced some weeks ago. They will witness an agricultural and horticultural exhibition, which is to be held at Bone, for the whole of Algeria and Tunisia, and which will be held in Algiers in 1881.

The most successful lecture this year at Montpellier, was organised by the Languedocian Society of Geography. MM. Soleillet, Brau de Saint Pol Lias, Director of the Sumatra Exploring Company, and other explorers or intending explorers, appeared before the public on that occasion. M. Rabaut, the President of the Society of Geography of Marseilles, and the commercial agent for the Sultan of Zanzibar, gave most interesting details of the several explorations at present going on in that part of the Dark Continent.

The lecture on the progress of electricity was given by M. Denayrouze, of Jablochkoff candle notoriety. The speaker tried to show that Jamin's candle ought to be superior to the light which is spreading so largely in Paris and in London.

Another lecture was delivered by M. Barral, Perpetual Secretary of the National Society of Agriculture, on the necessity of using Rhone water for irrigation. There is, however, a variety of opinion on this subject, commercial people being really opposed to the irrigation scheme for the reason that it would diminish the quantity of water necessary for navigation, especially as it is intended to submerge vines in order to save them from phylloxera, the plague of the country.

A very interesting display took place in the Polygon, of the destroying power of modern methods of warfare, as practised by French engineers of the 2nd Regiment, which is garrisoned in Montpellier. It cannot be said that science is alien to the use of dynamite and electric sparks for such purposes, but it is the first time that warfare has been considered as being really within the limits of a scientific association.

Two of the most interesting excursions were devoted to agriculture—one to the experimental grounds established by M. Marey, one of the most active correspondents of the Academy of Sciences, with a view to destroy phylloxera, and the other to the School of Agriculture directed by M. Camille Saint Pierre. This school, established with the help of the General Council only a few years back, has already reached a high point of prosperity. Its reputation is so high in the Mediterranean regions that the Greek Government is sending there a number of pupils at its own expense.

The Sericicultural Station has been placed under the direction of M. Maillot, a pupil of M. Pasteur at the Normal School of Paris, who has already instructed ninety-two persons in the difficult art of observing silkworms' eggs with microscopes.

At the Viticultural Station American vines, insecticide, and all the proposed means of destroying phylloxera are being studied.

All the pupils of the Normal School for public teachers, are attending a course of lectures in that establishment, so that the teachers of the young Herault peasants will have a scientific knowledge of new methods proposed for scientific agriculture of the region.

SCIENTIFIC SERIALS

American Journal of Science and Arts, August.—This number opens with the first portion of a paper by Mr. Upham, on terminal moraines of the North American ice-sheet.—Prof. Kimball describes experiments with regard to the effects of magnetisation on the tenacity of iron and on the flexure of a soft iron bar. *Inter alia*, he proves that a soft iron bar has its tenacity increased about nine-tenths of 1 per cent. by magnetising it to saturation.—Prof. Hilgard calls attention to some points in connection with the loess of the Mississippi valley, which seems to render the Æolian hypothesis untenable regarding that and similar deposits elsewhere; the hypothesis, viz., that the true loess is always a subaërial deposit, formed in a dry central region, and that it owes its structure to the formative influence of a steppe vegetation.—Dr. Cutter describes his method of micro-photography with Tolles's $\frac{1}{75}$-inch objective.—Prof. Peirce demonstrates the value of M. Faye's proposal of a method of swinging pendulums for the determination of gravity, and Mr. Hodges offers some considerations on the size of molecules, arising out of the conversion of water into steam, and the combining effect of platinum on hydrogen and oxygen.—Among other topics treated are the geology of Virginia, the discovery of a new group of carboni-

ferous rocks in South-Eastern Ohio, and the Laramie group of Southern Colorado and Northern New Mexico.

Journal of the Franklin Institute, August.—The following may here be noted:—Committee Report on the Fairbank's testing machine.—A new method of constructing index plates for gear cutters, by Prof. Sweet.—A new genus in telephones, by Prof. Dolbear.—On the use of determining slag densities in smelting, by Mr. MacFarlane.

Bulletin de l'Académie Royale des Sciences (*de Belgique*), No. 6, 1879.—Besides the paper of M. Montigny on the colour in scintillation of stars (elsewhere noticed), we note here an account of a new method, by M. Bruylants, for preparing hydriodic and hydrobromic acids, viz., adding iodine and bromine to the terpene contained abundantly in balsam of copaiba, and then detaching them under the influence of heat in the state of the corresponding acids.—The physiology of the muscles and nerves of the lobster is elucidated by MM. Fredericq and Vandevelde, who show that the only difference from superior animals is in the velocity of the nervous influence, this being, in the lobster, only 6 metres per second. Further, it is diminished considerably in the termination of the motor-nerves.—Mr. Macleod communicates a histological paper on the Harder gland in the domestic duck; and M. Schleicher writes on the living cartilaginous cell, the protoplasm of which he finds to consist of two different substances, one nearly liquid and homogeneous, the other, solid elements endowed with contractility (the nucleus is similarly formed).—M. Dubois describes some new birds.

No. 7.—M. Montigny here brings forward evidence that the principal star γ of Andromedes is subject to changes of colour, which are very probably periodic.—M. Plateau finds, in two notes by Brewster, confirmation of his views on the nature of irradiation.—A paper by MM. Masquelin and Swaen treats of the first phases of development of the maternal placenta in the rabbit, and M. Folie writes on some theorems relative to surfaces of superior order.

Journal de Physique, August.—On the temperature of the polar extremities of carbons producing the electric light, by M. Rossetti.—On Ampère's formula, by M. Jamin.—Researches on the compressibility of gases, by M. Cailletet.—M. Faber's speaking machine, by M. Gariel.

Reale Istituto Lombardo di Scienze e Lettere, Rendiconti, vol. xii. fasc. xiv.—On the problem of subdivision of the electric light, by Prof. Ferrini.—Observations of Swift's comet at the Observatory of Brera, by Prof. Schiaparelli.—Study on some crania of Araucanians and Pampas in the National Museum of Anthropology of Florence, by Dr. Riccardi.—Results of observations on the diurnal period of magnetic declination during 1872-77, at the observatory of Brera in Milan, by Dr. Rajna.—On the Mascart electrometer, by Dr. Maggi and S. Ascoli.—Experiments on the capillarity of water, by Dr. Poloni.

Fasc. xv.—On the transformation of the 11th order of elliptic functions, by S. Klein.—On special corpuscles (psorosperms) of man, by Dr. Grassi.—On the application of the dynamometer in operations of lithotrity, by Prof. Scarenzio.—Meteorological observations at the Observatory of Brera, in Milan, in 1878, by S. Frisiani.—Contributions to a study of the lias fauna of Lombardy, by Dr. Parona.

THE *Jahrbuch der k.k. geologischen Reichsanstalt* (Vienna, ii., April to June) contains an elaborate treatise by C. M. Paul and Dr. E. Tietze, entitled "New Studies on the Sandstone-zone of the Carpathian Mountains." The remainder of the part is taken up by a petrographical study on the granite of Predazzo, by A. Sigmund, followed by some geological and petrographical notes on the older eruptive and stratified rocks of the Middle and Eastern Alps, by Dr. Guido Stache and Conrad von John. The latter paper is the second communication these gentlemen have made on the subject, and treats specially of the Cevedale district as the distribution district of older dioritic porphyrites. It is accompanied by four well-drawn plates.—The *Abhandlungen* of the same Society (vol. xii. Heft 1) contain the first part of an excellent treatise by R. Hoernes and M. Auinger on the Gasteropoda of the marine deposits of the first and second miocene Mediterranean stages in the Austro-Hungarian Empire. The species here described belong all to the genus *Conus*, and are well reproduced on six magnificent plates. Thus we have illustrations of Chelyconus, Rhizoconus, Lithoconus, Dendroconus, Liptoconus, and Stephanoconus, representing some fifty-two different varieties.

SOCIETIES AND ACADEMIES

LONDON

Entomological Society, September 3.—J. Jenner Weir, F.L.S., F.Z.S., treasurer, in the chair.—Mr. Philip B. Mason exhibited specimens of *Harpalus oblongiusculus*, Dej., taken at Portland, and also, on behalf of Mr. Gameys, specimens of *Euplectus ambiguus*, Reich., found in flood refuse at Repton.—Miss E. A. Ormerod read "Notes on the Prevention of Cane-borers."—Mr. Jenner Weir exhibited a pair, male and female, of *Cicada montana*, Scop., taken at the New Forest, Hampshire.—M. Ch. Oberthur communicated the following paper: "Observations sur les Lépidoptères des Îles Sangir et Descriptions de quelques Espèces nouvelles."

PARIS

Academy of Sciences, September 8.—M. Daubrée in the chair.—The following papers were read:—On the mean value of numerical coefficients in a skew determinant of order infinitely great, by Prof. Sylvester.—Pathological predisposition and immunity; influence of origin or of race on the aptitude of animals of ovine species to contract splenic disease, by M. Chauveau. Algerian sheep seem to enjoy immunity from this disorder. M. Chauveau selected nine from different lots of authentic origin in the Lyons market (to which large numbers are imported). Notwithstanding repeated inoculation (three and five times), none of them showed multiplication of the *Bacillus anthracis*, characteristic of the disease. On the other hand, French sheep and rabbits all succumbed after the first inoculation. M. Chauveau urges the importance of this question of special immunity.—The President expressed the lively satisfaction of the Academy at M. Nordenskjöld's return.—On the causes of reinvasion of phylloxerised vines, by M. de Laffitte.—On the same subject, by M. Cauvy.—On the compounds of hydracids with ammonia, by M. Maumené. Some observations on the *rôle* of insects during the flowering of *Arum crinitum*, Ait., by M. Schnetzler. Of the flies attracted by the fetid odour of this Arum, those most pressed to lay, deposit their eggs at the bottom of the spathe; then, prevented escaping by the viscous hairs at the entrance, they die. Others, less pressed to lay, are attracted by the glandular hairs on the spadix, which lead them, like the degrees of a scale, to the stamens. There, walking on the anthers, they liberate the pollen, and remounting the spadix in the direction of the hairs, they fly off to lay their eggs in another spathe, at the bottom of which they deposit on the stigmata the pollen brought from the stamens of another individual; then, imprisoned in their turn, they die. The purple red hairs covering a good deal of the interior surface of the spathe probably contain an acid which, like that exuding from the hairs of Drosera, may contribute to transformation of the azotised matters of insects into matters absorbable by the spathe.

THE AGRICULTURAL ANTS OF TEXAS

The Natural History of the Agricultural Ant of Texas: a Monograph of the Habits, Architecture, and Structure of "Pogonomyrmex barbatus." By Henry Christopher McCook. Author's Edition. Academy of Natural Sciences of Philadelphia. 1879. (London: Trübner and Co.)

THE agricultural ant of Texas was first introduced to the English public in 1862, by means of a communication from Dr. Gideon Lincecum to Mr. Darwin, published in the *Journal* of the Linnean Society of London, and much interest was excited by the account given of an insect which actually sowed seed, tended the crop, and reaped the harvest. No further information being forthcoming, doubts were expressed both here and in America as to the accuracy of the observations, and Mr. McCook went to Texas in the summer of 1877 for the express purpose of testing them. Unfortunately, however, he could only stay about three weeks, which he devoted entirely to observation of the ants. He however obtained information from residents, and carried away some living ants on which to make further observations at home, and the result is given in much detail in a handsome volume of over 200 pages, illustrated by a series of twenty-four plates, giving details of the nests, the attitudes, the habits, the external structure and internal anatomy of the species in question, and some of its allies.

With all this elaboration, however, the main point still remains in doubt, and Mr. McCook does not and cannot tell us whether the agricultural ants really do sow the seed, though they undoubtedly reap the harvest. What he does tell us, however, is sufficiently curious. The insect is a true harvesting-ant, like those so well described by Mr. Moggridge, but it differs from all other species in forming large cleared disks on the site of its nests. These disks vary from two to twelve or fourteen feet in diameter, and are approximately circular, and however thick may be the grassy or weedy vegetation around them the disks are perfectly bare and smooth and thus form very conspicuous objects in the landscape. The openings to the nests and granaries are near the centre of the disk, and in some cases are formed in a central convex or conical mound, while in others the surface is entirely flat. In about one-third of the nests examined by Mr. McCook, the outer border of the disk, sometimes for two feet wide, was covered by a crop of ant-rice (*Aristida oligantha*) differing wholly in appearance and colour from the surrounding vegetation, just as a crop of wheat or oats differs from a field of mixed herbage, while not a solitary weed of any kind was to be found in the belt of ant-rice.

Lincecum had stated that the seeds of the ant-rice were regularly sowed in the autumn, kept weeded during winter and spring, and reaped in summer. Mr. McCook was only able to see the last stage. The plant had certainly been weeded; its seeds were found in the granaries mixed with many others; and, it is admitted "that there is nothing unreasonable, or beyond the probable capacity of the emmet intellect, in the supposition that the crop is actually sown. Simply it is the Scotch verdict—not proven." This is very unsatisfactory, and as the journey appears to have been undertaken for the express purpose of testing this, the only incredible part of Lincecum's observations, it seems curious that it should have been made in July, at the time of the harvest, instead of in November, the time of the alleged sowing of the crop. If we reject the "sowing" as too improbable, the only other explanation of the facts seems to be that the *Aristida* is one of those singular plants which constantly appear on cleared ground although not growing in the immediate vicinity, and that the ant's clearings prepare the conditions for its growth. A few experiments would soon test this, and it is a great pity some resident could not be found to determine this most interesting point either by observation or experiment. The book is, however, full of valuable matter as to the habits and actions and the whole domestic economy of ants; and there is a useful chapter on "the ancient belief in harvesting ants—how it was discredited and how restored," in which the opinions of many ancient and modern authors are given with a number of suggestive extracts from the classics as well as from the Rabbinical laws and traditions. We cannot, however, but feel some regret that the author did not make more extended observations before writing so voluminous a work, so that he might have been able to clear up the numerous points now left in uncertainty. The chief authority for a number of important statements is still Dr. Lincecum, who appears to have resided for many years in Texas and to have assiduously studied the habits of the ants, and there does not seem to be any essential point in which Mr. McCook's own observations show his predecessor to have been in error. On the contrary he must be considered to have proved the substantial accuracy of the doctor's facts so far as he was able to do so in the limited time at his command.

ALFRED R. WALLACE

EXPERIMENTAL GEOLOGY

Études Synthétiques de Géologie Expérimentale. Par A. Daubrée, Membre de l'Institut, Directeur de l'École Nationale des Mines, &c. (Paris: Dunod.)

MONSIEUR DAUBRÉE has, during the last thirty years, published numerous very important memoirs describing the production, upon a small scale in the laboratory, of various natural geological phenomena. These papers, which were originally scattered through the pages of different scientific journals, are now for the first time brought together. The first part of this work, under the title of "Application of Experimental Methods to the Study of Various Geological Phenomena," forms a handsome and well-illustrated volume of nearly five hundred pages. This is to be followed by a second part, to be entitled "Application of Experimental Methods to Various Cosmological Phenomena," which will describe investigations recently made on the constitution and characteristics of meteorites.

The earlier portion of the volume before us details the results of numerous experiments made with the object of explaining different geological phenomena, of which some are chemical and physical, while others are simply mechanical.

To the first class belong the history of mineral deposits, of crystalline rocks, both eruptive and metamorphic, and of the different forces producing vulcanicity.

Among the phenomena belonging to the second category are the formation of pebbles, sand, and clay, as well as sundry other effects of trituration and transport. The distortions and ruptures of the earth's crust, such as the production of faults and joint-systems, also belong to this division, which includes the origin of the schistosity and cleavage of rocks, the distortion of fossils, and certain peculiarities in the structure of mountain chains. Lastly, the author treats of the temperature developed in rocks by mechanical action.

Among the more striking and instructive experiments for which science is indebted to M. Daubrée, are those in which glass tubes partially filled with water are incased in tubes of iron, also containing water, and subjected for lengthened periods to a high temperature at a pressure of above one thousand atmospheres. By this treatment not only was the glass decomposed, but crystalline quartz presenting all the characteristics of natural crystals of that mineral was produced. Crystals of pyroxene were obtained by the same means, and fragments of wood similarly treated were converted into anthracite.

The formation of various crystallised zeolitic and other minerals, such as chabazite, christianite, and calcite, in the masonry of the Roman baths at Plombières and the deposit of mammellar opal by their waters, teach the importance of time as a factor in such transformations. In this case the different minerals, instead of being rapidly produced at a high temperature have been slowly developed at a low heat and without appreciable increase of pressure. Numerous coloured illustrations are given as seen under the microscope, of thin sections of Roman bricks inclosing zeolites in their cavities, and attention is directed to the fact that in one instance at least the structure of the mass has been rendered distinctly fluidal by pressure applied to the clay in making the original brick.

The production of numerous well-crystallised metallic minerals by the action of the waters of Bourbonne-les-Bains upon a quantity of Roman bronze coins and on some ancient lead piping, which had been for centuries subjected to its action, is an equally curious and instructive fact. These waters issue from the earth at a temperature of 58° C., and contain soluble matter to the extent of from seven to eight grammes per litre. This consists of alkaline chlorides, bromides and sulphates, chlorides and sulphates of calcium and magnesium, alkaline silicates, and traces of arsenic and manganese. In addition to these substances various others are present in subordinate quantities.

Among the well-crystallised minerals resulting from the action of water upon the metals and alloys present, cuprite, redruthite, chalcopyrite, tetrahedrite, phosgenite, anglesite, galena, and iron pyrites were recognised and examined.

The investigations bearing upon the history of volcanic phenomena, which demonstrate that an infiltration of water can take place through a porous medium in spite of a high steam-pressure operating in a contrary direction, are both valuable and suggestive, and the experiments on such mechanical questions as the causes of the contortion of strata and of the faults and jointings in rocks, throw much new light upon those obscure questions.

In its complete form M. Daubrée's treatise will represent the life-work of a trained and careful investigator in an almost untrodden direction, and will form the first text-book on experimental geology. The portion now published cannot fail to be read by geologists with great interest and profit, and we trust the time is not far distant when experimental geology will have become a generally recognised branch of geological investigation.

J. A. P.

OUR BOOK SHELF

Annual Record of Science and Industry for 1878. Edited by Spencer F. Baird, with the assistance of eminent men of science. (New York: Harper Brothers; London: Trübner, 1879.)

It again becomes our pleasant duty to call the attention of our readers to the excellent annual record of science edited by Mr. Baird, Secretary of the Smithsonian Institution. We think the editor has done wisely in discontinuing the division of the record into two parts, for hitherto the summary of progress has been followed by abstracts of papers. At present the second part has been merged into the first, so that summary of progress in the various branches of science now includes a large amount of detail; each summary being prepared by some recognised authority in the United States. As we have had occasion to remark before, the division on the physics of the globe, prepared by Mr. Cleveland Abbé, with the assistance of Prof. Rockwood, is, in our judgment, the most important contribution to the volume. The compilation and classification of the facts presented in this summary must have been a work of great labour, and the thanks of all physicists and meteorologists are due to Mr. Abbé for having so admirably carried out the task he has undertaken.

The summary of physics and chemistry seems to us somewhat incomplete; there is no reference, for example, to the new forms of stereoscope invented by Mr. Grubb, nor to the remarkable memoirs published by Mr. Johnstone Stoney during the past year in the *Transactions* of the Royal Dublin Society; in fact, the omission of all mention of the active work done by this flourishing society is a serious oversight of the editor.

The value of the summary of physics and chemistry would also be much enhanced if, instead of abruptly beginning each paragraph with the name of the investigator, the nature of the investigation were put first, and a reference given in each case to the publication where fuller details could be found We trust that this last—a most important point, which is carried out in some of the reports, will next year be extended to all.

Greater editorial care seems also required in bringing about a more uniform system of classification throughout the volume, and the omission of repetition—take for example Prof. Jevons' paper on Pedesis, which is twice described in detail on pp. 216 and 376. Why, too, amongst British journals of pure and applied science are the *Quarterly Journal of Science*, the *Telegraphic Journal*, the *Electrician*, and *Engineering* omitted, whilst *Iron* is included?

We make these remarks in no captious spirit, but with the real desire to augment the usefulness of this work. For the same reason we would urge the paramount importance of having, in addition, an English and a Continental editor. It is impossible for a work of this kind to be otherwise thoroughly done, nor can a proper appreciation (often lacking in the volume before us) be shown, of the relative merit of the investigations scattered over the

numerous scientific journals of to-day. We look forward to the time when the *Annual Record of Science* will become a standard work absolutely indispensable to all libraries, both public and private, at home and abroad.

W. F. B.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Heat of the Comstock Mine

I NOTICE in NATURE, vol. xx. p. 168, that Dr. Lesley quotes from Prof. Barker an opinion in regard to the heat of the Comstock Mines in Nevada. Referring to my assertion that the heat of the rock "is pretty uniform" in the lower levels, Prof. Barker announces that there are "the most remarkable differences, some of the higher levels being much hotter than some of the lower levels." This is perfectly true, and the fact is no disproof of my assertion. In the article to which Dr. Lesley refers (*Silliman's Journal*, April, 1879) I said that there are striking differences of temperature in the rock, and endeavoured to explain them by showing that there is a great mass of rock which may be regarded as heated to a tolerably uniform degree at all points in the length of the lode, on any given level, and that in this general mass there are isolated localities, most of which show a temperature above that of the rock at large, but some of them below it. I pointed out the conditions under which these local maxima occur, and gave the explanation to which I thought they led. The hot spots are evidently narrow and long, and as the mine openings sometimes intersect and sometimes follow them for some distance, a given level will be for a part of its length in a hot belt and for a part in the general mass of heated rock, or one level may be in a hot belt and show a much higher temperature than the level below, which entirely escapes the exceptionally hot ground. In this way thermometric variations are obtained between different levels and between different parts of the same levels, and these facts were all brought out in my article.

I should not trouble you with this explanation did I not feel that the Comstock lode bids fair to become a classic field for the discussion of terrestrial temperatures. Mr. Clarence King is now on the ground, and will, no doubt, make its unrivalled heat phenomena the subject of careful examination, and everything that bears upon the question has importance.

Dr. Lesley expresses some doubt upon the mechanical theory of earth-heat which was one of Prof. Barker's two conclusions upon the source of the heat. The Comstock is certainly good ground to test this question, for I have never witnessed such constant and general movement of the rocks in any other mines. Still, I do not share Prof. Barker's opinion on this, or on his other point, "that the heat is a hot-water heat." No mining engineer would pronounce the Comstock a wet lode. It discharges four and a half million tons of water yearly, and yet out of the more than twelve miles of linear excavation made every year, I do not believe that 1,000 feet are in ordinarily wet ground. It is a dry lode for the greater part, and in writing upon the subject my efforts have been directed to seeking an explanation for the extraordinary temperature of this dry rock.

JOHN A. CHURCH

115, Broadway, New York, September 8

Crossley's Modification of Hughes's Microphone

EVER since Hughes's discovery of those principles which led to his invention of the microphone, inventors have been trying to improve the instrument by adopting every variety of form and employing every combination of apparatus that were likely to lead to good results. The failures must have been legion, and of the successes the members of the British Association have had during their stay at Sheffield, an opportunity of examining and seeing at work perhaps the most efficient—Crossley's modification of the microphone. Six distant places—the two newspaper offices and four meeting-rooms—were telegraphically connected with the Cutlers' Hall, where a switch-board stood to place any two distant stations into communication, thus illustrat-

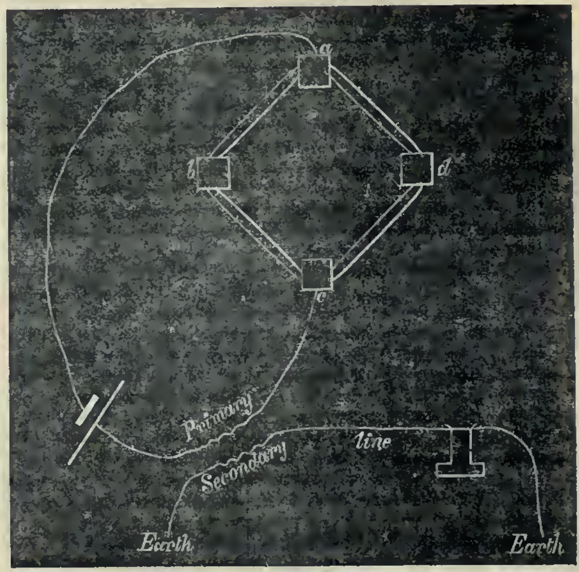

FIG. 1.

ing the exchange system so largely employed in America. Every one is aware that with the telephone the speaker has to hold the

FIG. 2.

instrument to his mouth; with the Crossley's transmitter, however, conversation, a few feet away, is readily conveyed. The transmitter is now being largely employed in the United King-

dom, and it is found that where telephones alone are useless because of the induction of adjacent wires, the instrument acts admirably. The undulatory current produced by sonorous vibrations is so intense that a person speaking about a foot away from a transmitter has been heard ten feet from an ordinary telephone in Manchester thirty-six miles away by wire, and this although the induction from some thirty adjacent wires had to be overcome, and we may add that the intensity of the sound may be largely augmented by employing increased battery power.

Four carbon pencils are nicely centred and loosely held in four blocks of carbon, *a b c d;* two opposite blocks, *a* and *c*, are connected in circuit with a battery and the primary wire of an induction-coil. The efficiency of the arrangement is now made complete by having a telephone in the secondary circuit. The carbon blocks are mounted on a thin wooden diaphragm, and consequently are not seen in Fig. 3, which represents one form of the finished instrument.

For some months past an interesting and highly successful operation has been made every Sunday. One of these trans-

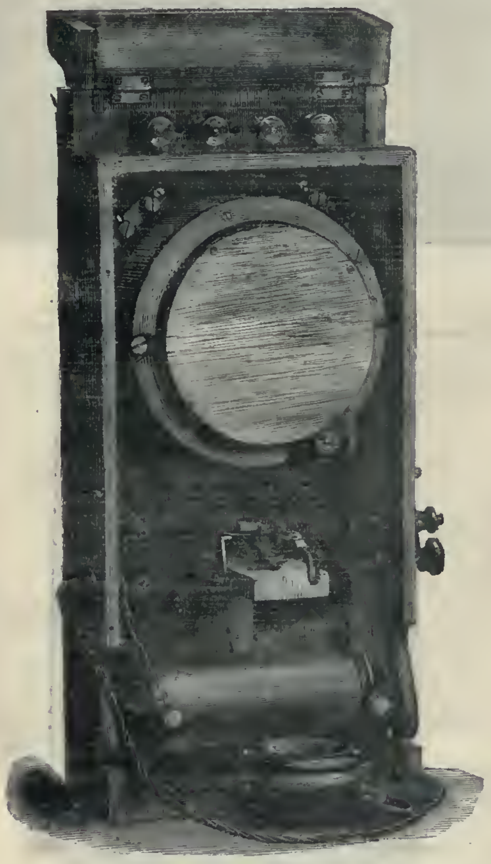

Fig. 3.

mitters is fixed in the pulpit of one of the Halifax places of worship. Its position is not over-favourable, being half hidden so as to escape attention, and thus to some extent its efficiency is interfered with. In the nether regions, where the organ-blowing apparatus is found, a Clamond's thermo-electric pile is placed, and one of the first duties of the sexton on a Sunday morning and evening is to light a gas jet under the pile. In this way a sufficient supply of electricity is obtained to work exceedingly well at a cost of less than 2*d.* per Sunday in gas consumed. On the outskirts of the town several houses have telephones in the secondary circuit, one of these belonging to an invalided lady, and the service, from the opening voluntary to the parting benediction, is heard plainly by every one. The rendering of the music is especially fine, sounding to the observer, sat at ease in an arm-chair, as if proceeding from a neighbouring room with the door slightly ajar.

William Ackroyd

Colour-Blindness

When your able reviewer Prof. Pole so plainly intimates, in Nature, vol. xx, pp. 477 to 480, that he does not consider any of the theories of colour-blindness he has mentioned to be altogether sufficient for the observed facts, and that he may return to the subject in a future number, I trust he may then take some notice of my views, as honoured by the Royal Society, Edinburgh, in vol. xxviii. of their *Transactions*.

At all events, it is much to be hoped that in his own future descriptions, he will define his colours more accurately than by the naked eye estimations and names of even those who are allowed to possess normal vision. For, as I have shown in the paper above alluded to, there are physical distinctions, amounting to more than the oppositions of black and white, and reacting on colour, between many pigments generally reputed by the world to be all of the same colour to the eye.

To speak therefore of green, or red, or brown is nothing; but it is what green, and what red, and what brown that must be settled, as a preliminary to any further safe observation on the subject.

Piazzi Smyth

15, Royal Terrace, Edinburgh, September 19

The Carving of Valleys

In the course of a recent visit to Loch Maree, I observed an interesting geological phenomenon in a glen on the east side of the loch, which is traversed in ascending Ben Slioch, from Kinlochewe, and which is called, I understand, Glen Beansdale. This glen, in its lower part at least, follows the line of division between the "fundamental gneiss," which rises in a gradual slope on the north side, and the "Cambrian sandstone," which on the south side forms a fine cliff, terminating at the base in a long steep "*débris* line." The stream, which is of considerable size, originally ran close to the foot of this cliff until it reached the wide valley which contains the loch; but at some period a large "bergfall" of rocks from the sandstone cliff has dammed up the original bed, and diverted the stream into a new course, diagonally across the gentle slopes of gneiss, which previously formed the north side of the glen. This new course is marked, first, by a small depression or gully in the flow of the glen, and secondly, in the middle of this, by a narrow ravine with vertical sides, just wide enough to contain the stream which foams at the bottom.

There is nothing in itself very remarkable about this diversion of a stream; but the point which gives the case its interest is that an inferior limit can be fixed for the time at which the diversion took place. For, on descending into the secondary depression above mentioned, I was able to trace the glaciation, or planing down by ice of the edges of the gneiss (which was admirably clear on these slopes) right down to the brink of the little ravine containing the stream, thus showing conclusively that the diversion had taken place *before* the glacial period, and so long before that the stream had time to cut a channel sufficient to guide the glacier in its flow, and divert it from the work it would otherwise have accomplished in clearing away the remains of the berg-fall, and re-opening the old river-course. Thus it will be seen that in the new channel we have an example of the work which can be done by a mountain stream during a period dating back at least beyond the glacial epoch; while the old channel exemplifies the work done in the same time by the various agencies of "sub-aërial waste"—rain, wind, frost, &c.—without a stream to assist them, either by direct erosion of its own or by sweeping away the *débris* which they had brought down.

What, then, are the phenomena presented by these two cases? In the first, the only work which can really be ascribed to the stream is the cutting of the deep narrow gorge at the bottom of which it now runs; for with regard to the wider depression above (itself a mere furrow in the main flow of the glen), it is impossible to say how much has been due to the planing action of the ice. In the second, the bottom of the old channel, if there be any power in "sub-aërial waste," should be choked by the *débris* which has come down from its sides, whereas I was easily able to detect live rock within a few feet of the tiny runnel which now drains the gully, and which itself picks its way among stones and boulders that are clearly nothing but the cumbered bed of the old-world torrent.

The question I wish to ask is whether the study of these two examples is not sufficient to produce something like a conviction that the modern school of geologists (as worthily represented by

the President-Elect of the British Association) is after all in error, and that the true agency which has carved out our valleys and given us our mountain scenery is still to seek. The evidence of the new channel agrees with that to be found elsewhere (on its grandest scale in the cañons of North America), in showing that the action of streams is to excavate not open valleys, but narrow and vertical clefts. On the other hand, the agencies of "sub-aërial waste" are seen to have worked their will for untold ages on the Cambrian sandstone of Glen Beansdale, and to have produced—nothing. They have not even removed the blocks of the old berg-fall, which looked as if they might have fallen within the memory of man, instead of at a date which must be reckoned by thousands, if not millions, of years. There remains the power of ice, which I am by no means disposed to undervalue; but the traces of the last "glacial period" are in this case clear enough, and amount at most to a slight deepening of the lower part of the glen, while to assume previous and much more intense glacial action, of which no direct evidence remains, would scarcely be justifiable. WALTER R. BROWNE

A "Nightly Resurrection"

YESTERDAY, in the *Pall Mall Budget* of July 11, 1879, p. 22, in a review of Mr. Stevenson's—"Travels with a Donkey in the Cevennes," I read the following, which is an extract of Mr. Stevenson's book. It is a very interesting observation. He slept a good deal under trees at night, and he says: "And there is one stirring hour unknown to those who dwell in houses, when a wakeful influence goes abroad, and all the out-door world (meaning animals and men who sleep in the open) are on their feet. It is then that the cock first crows. . . . Cattle awake in the meadows, sheep break their fast on dewy hill-sides, and change to a new lair among the ferns; and houseless men, who have lain down with the fowls, open their dim eyes and behold the beauty of the night. . . . Even shepherds and old country folk, who are the deepest read in these arcana, have not a guess as to the means or purpose of this nightly resurrection. Towards two in the morning they declare the thing takes place, and neither know nor inquire further."

This is a very curious and interesting fact, but Mr. Stevenson is mistaken when he states that this "stirring hour," "when a wakeful influence goes abroad," between the hours of *one and two in the morning*, is unknown to those who dwell in houses. I have been aware of it for a long time, and have noticed it year after year on myself, although I dwell in a house. In the winter I usually go to sleep at 9 P.M., and then feel cold and require a good deal of bed covering to keep me warm; but between one and two in the morning I feel uncomfortable, wake, and feel hot, and am obliged to throw off some of the bed-clothes. Afterwards this discomfort passes away, I pull over me the blankets again, and go to sleep till daylight. This occurs morning after morning as regularly as possible.

In the summer I awake as regularly as possible about the same hour, and feel uneasy and toss about for some little time, although at this season no blankets are used, and then go to sleep again.

Since I have been at Fyzabad I have been able to test more accurately the hour in which this wakeful influence begins to occur. I used to awake at the usual hour, and while awake I invariably heard the railway whistle of the train which leaves for Lucknow at 12.50 A.M. Latterly I have not been noticing this whistle, and I am not aware that I wake at that hour, but there has been and is plenty of rain during this rainy season, saturating the soil and atmosphere with moisture. Probably this moisture may prevent that subtle "wakeful influence" from reaching the nervous system. Again, I am rather subject to an occasional neuralgic pain on the left side of my forehead. When this occurs at night, it goes on increasing to its *maximum* between one and two o'clock in the morning, and afterwards it begins to subside. I often suspected that some change in the *terrestrial magnetism* some time after the passage of the sun across the meridian, on the other side of the earth, may be the cause of this "subtle influence." Perhaps those who take observations on terrestrial magnetism may throw some light on this subject. Whatever may be this "subtle influence" which acts on the nervous system of animals between *one and two o'clock* A.M., there is a similar influence in the *day*, between one and two P.M., although it may not have been noticed. I have observed it, because when I get the before-named neuralgic pain in *the day*, it goes on increasing till between one and two o'clock P.M., when it begins to subside. This question arises: are the periodical exacerbations in fever and neuralgias, &c., due to some similar cosmical influence? Statistics on these points are worth collecting. It is natural to suppose that the nervous system of animals—a most sensitive tissue—would be readily influenced by any magnetic change of the earth, or by other subtle cosmical influences. E. BONAVIA

Fyzabad, August 19

A Habit of Cattle

MR. H. C. DONOVAN, in a letter headed as above (NATURE, vol. xx. p. 457), describes the bone munching of cattle in Natal, and asks whether they have a similar habit in other places. Such is the case in Norway, especially at the upper pasturages around the "saeters," or mountain chalets, where they are commonly supplied with a daily modicum of fish-bones and salt, which they eat with great avidity. There is but little lime on the Norwegian fjelds, the prevailing rock is mica schist.

Stonebridge Park, Willesden, September 17

W. MATTIEU WILLIAMS

Intellect in Brutes

LAST year we spent our holiday at Llan Bedr, Merionethshire. Our host has a house in the above village and another at Harlech, a town three miles distant. His favourite dog, Nero, is of Norwegian birth, and a highly intelligent animal. He is at liberty to pass his time at either of the houses owned by his master, and he occasionally walks from one to the other. More frequently, however, he goes to the railway station at Llan Bedr, gets into the train, and jumps out again at Harlech. Being, most probably, unable to get out of the carriage, he was on one occasion taken to Talsarnau, the station beyond Harlech, where he left the carriage, and waited on the platform for the return train to Harlech. If Nero did not make use of "abstract reasoning" we may as well give up the use of the term.

Manchester, September 20 WILLIAM HORSFALL

BERNHARD VON COTTA

ON the 14th inst. at Freiberg, in Saxony, this distinguished geologist breathed his last. Science has lost in him an ardent and conscientious follower, one in whom great powers of observation and reflection were harmoniously associated. He possessed in especial that "combining understanding" which Alexander von Humboldt so highly prized.

The youngest of four sons of the late Oberforstrath v. Cotta, of Tharand, in Saxony—a man celebrated as forester and founder of the Forstacademie in that picturesque little town not far from Dresden—Bernhard was born, October 24, 1808. His father had taken a great interest in natural sciences, and had much occupied himself with palæontology; and Bernhard appears to have inherited this taste. Early in life he was a student at the Freiberg Mining Academy—where he subsequently became Professor of Geology—and he likewise studied at Heidelberg and received a degree as Doctor of Philosophy. His intellectual activity soon became strongly pronounced and led, from the attainment of manhood till near the close of his life, to the publication of numerous valuable works. Whilst still a student at Freiburg, his first work, "Die Dendrolithen," was written (published 1832). Subsequently, associated with Prof. Naumann, he worked at the geological map of Saxony, which was published in twelve sections, and he afterwards alone completed a similar work for Thuringia. In 1836 appeared the first part of a work entitled "Geognostische Wanderungen," and in 1838 a second part; in these the principal geological features of the kingdom of Saxony are described and explained. He likewise wrote other works of great practical value, of which "Gangstudien," "Lehre von der Erzlagerstätten," and "Gesteinslehre" deserve most favourable mention. Of more theoretical value is a work which has gone through many and enlarged editions: "Anleitung zum Studium der Geognosie und Geo-

logie," the first edition of which appeared in 1839. Other works of like character by the same prolific author are: "Ueber den innern Bau der Gebirge" (1851), and "Geologische Fragen" (1858). In these works Bernhard von Cotta has shown himself to belong to the school of Lyell in so far as he holds unlimited time to be necessary for the explanation of geological processes.

The way in which natural sciences generally, and geology in especial, were grasped in Cotta's large and practical mind caused him earnestly to desire that geology should be more generally known and appreciated by men of average education, and he consequently published several works which, in the best sense, may be called popular. To these belong his "Letters on von Humboldt's Cosmos" (2 vols., 1851–52), "Geological Letters from the Alps" (1850), "Geological Pictures" (1852), "Catechism of Geology" (3rd edit., 1877), and last, not least, deserving mention, is his great work: "Geologie der Gegenwart" (the present state of geology), the 1st edition of which appeared in 1866, the 5th, partly re-written and enlarged, in 1878. These works have greatly contributed to put an end to those fantastical ideas about geology which so long prevailed, even amongst well-educated classes; and by promoting a sound understanding of geological states and processes, and of their bearing on practical life, they have done much to raise natural sciences in general estimation. Cotta's work, "Deutschlands Boden," must also here be named. Not only does it contain information of great importance to agriculturists, miners, and manufacturers, but statesmen, politicians, and sociologists may benefit much from studying it. It makes it plain that geology forms the basis of geography, that the outward forms we see on the surface of the earth have for the most part been inwardly conditioned. A German critic has called this work "Epochemachend," and viewed it as a first attempt to show clearly by particular instances "the influence of geological formations on the life of man."

Cotta's "Geologie der Gegenwart" merits more notice than I can here bestow upon it. It contains fifteen chapters or separate essays on that science and important subjects therewith connected. Two of these essays: "On Geology and History," and "The Development Law of the Earth," have been published by me in English. In this work the author has shown himself to be an evolutionist and a thorough adherent of Darwin's theory of the origin of species. He was one of the first—if not the first—eminent geologist who fully accepted this theory and applied it to the organic remains in sedimentary rocks. And that which in Germany has been called "Cotta's development law" is admirable and fascinating by its simplicity.

More than once has Prof. v. Cotta been in this country. On his first visit (1836)—when he made the acquaintance of Lyell—I had the pleasure of accompanying him from Germany. He has also travelled in France, Northern Italy, Tyrol, Switzerland, Hungary, the Banet, Transylvania, and the Carpathians, and has written many articles in various periodicals on his geological observations, &c., in those lands. The number of his monographs and fugitive essays would fill a good-sized volume. Many of his earliest excursions were undertaken in the company of his friend, the celebrated geologist, Leopold von Buch; Cotta likewise enjoyed the friendship of Alexander v. Humboldt, with whom he often corresponded. In 1868 he was invited by the Russian Government to visit the Altai Mountains to report on their geological formation, minerals, &c. On his return to Freiberg he wrote an account of his journey and observations, and in 1871 published a large volume "Der Altai: sein geologischer Bau und seine Erzlagerstätten."

All the writings of Cotta are remarkable for lucidity, terseness, and logical reasoning. In all the desire is apparent to discover by the inductive method that connection of things which—even when most difficult or impossible to perceive—we know must of necessity exist. Owing to this tendency of his mind he has been said to belong to the School of Positivists. Many of Cotta's works have been translated into other languages. His "Gesteinslehre" Mr. P. H. Lawrence has admirably given in English: "Rocks Classified and Described," &c. Numerous German and foreign academies and learned societies have bestowed upon him honorary membership, and foreign potentates have given him decorations. As long ago as 1867 von Cotta became a Foreign Correspondent of the Geological Society of London, and within the last few months the highest honour in the gift of that Society was conferred upon him by his election as Foreign Member.

In private life, as in his scientific pursuits, Bernard v. Cotta was characterised by truthfulness and directness of purpose, whilst to these qualities were added warmth and fidelity in his attachments, and also kind consideration for the feelings and wants of his fellows in general. Thus his memory will live not only in the love and esteem of a widow and three daughters, but will likewise be cherished by those who have enjoyed his friendship. I may add that Cotta, like nearly all men of genius, was absolutely free from pedantry; that he was sympathetic and readily interested in politics, general literature, and social life. He possessed, too, a strong sense of wit and humour, and could greatly enjoy a good joke. R. R. NOEL

A ZOOLOGICAL STATION AT SYDNEY

SEVERAL references to the scheme for the foundation of a zoological station at Sydney having appeared in NATURE since the idea was first mooted by Dr. Miclucho Maclay, it may be of interest to our readers to learn how far the project has progressed in the meantime.

A correspondent in Sydney informs us that the Government of New South Wales have granted an allotment of land for the purpose at Watson's Bay, a small watering-place about six miles from Sydney (with which there is communication by steamer several times daily), and close to the entrance of Port Jackson. The site is an excellent one for the purpose, having a frontage of about 125 feet to Port Jackson, with good dredging-ground within a stone's throw, and so near the open Pacific (though entirely sheltered) that pelagic organisms may be obtained abundantly with the tow-net without going many hundred yards. The New South Wales Government have also promised the sum of 300*l.* towards the expense of erecting the building, which sum will be placed in the hands of the trustees when an equal amount has been raised by private subscription. The 300*l.* must be subscribed within a year, failing which the conditional promise of Government assistance will be withdrawn. As yet the subscription list does not show a total of one-third of the required sum; a circular soliciting subscriptions has therefore been issued to such in Sydney and elsewhere as are likely to take an interest in the matter. The money having been obtained, it is intended to proceed with the building on the plan proposed by Dr. Maclay. According to this plan the building will consist of two stories, the lower occupied, in addition to a small sitting-room or vestibule, by several (most probably four) well-lighted work-rooms, with dissecting- and microscope-tables, aquaria, and other necessary fittings. Each laboratory will be for the accommodation of a single worker, and will communicate by a separate stairway with a bed-room on the upper storey. Those working in the station will, by this arrangement, be able to live quite independently of one another, and to work without disturbance or interruption. In the upper storey there will also be a large common room or library communicating by a stair with the vestibule. A photographic room will be built in the rear, and a boat-

house with boat, dredges, and other collecting gear will be added. The whole will be so arranged that additional accommodation may be added when found desirable.

We need not point out the importance of the station proposed to be erected in Sydney. It is expected that most of those who will make use of the station will come from England, and therefore it will be only fair that English biologists should help our Sydney friends to complete the 300*l.* required for the station. There is some fear that they may not be able to raise the whole sum in the colony, and we would therefore strongly urge upon those of our readers interested in the enterprise to lend a helping hand. Dr. J. C. Cox, Hunter Street, Sydney, acts as treasurer, and Mr. George Leslie, assistant to Sir Wyville Thomson, University, Edinburgh, has been asked to become treasurer for any subscriptions that may be raised at home.

Baron Maclay, we may state, is at present engaged in an excursion in Polynesia, and will return to Sydney about the end of the present year.

THE RESIGNATION OF DR. ANDREWS

WE learn with great regret that Dr. Andrews has resigned the post he has so long held as vice-president of Queen's College, Belfast, and Professor of Chemistry. Dr. Andrews had been urged by his brother professors to allow himself to be proposed for the first vacancy in the presidency of the College, but his sense of duty urged him to give a peremptory refusal.

With reference to Dr. Andrews's work both as a professor and as a scientific worker, we quote from an excellent article in the *Northern Whig* of the 18th inst.:—

"Before the formation of the Queen's University he had been Professor of Chemistry in the medical school of the Belfast Institution, and from this post he was transferred to a similar chair in Queen's College, while at the same time he was appointed its first vice-president. The importance of this latter office may be gathered from the fact that to a joint board, consisting of the presidents and vice-presidents of Belfast, Cork, and Galway, was remitted the arduous task of framing statutes and ordinances for the internal management of the colleges, and on this board there was certainly no stronger man than Dr. Andrews. The Queen's Colleges were launched upon the country as a great educational experiment. Founded upon the principle of united secular and separate religious instruction, they had to contend all through their career against opposition of the bitterest and most unscrupulous character. The men, therefore, who actually worked the vessel through its early dangers have deserved well of their country in no small degree, and in the front rank of these stands Dr. Andrews. And not merely was he a practical worker in the cause of united education; he has besides given to the world some of the most effective expositions of its principles. His address on the subject, delivered in 1867 to the Social Science Congress in Belfast, is one of the classics of the question, and it is not too much to say that its influence was powerfully felt in moulding opinion in England in preparation for the Liberal educational policy of 1870. Nor was he a less well-recognised authority in regard to the general question of university education. His little work entitled 'Studium Generale,' elicited, if we mistake not, by the supplemental charter proposals, contains a most fresh and vigorous enunciation of the most enlightened views upon higher education. As a teacher of science, Dr. Andrews has been most successful. His mastery of the subject found expression in exposition of the clearest and most lucid character, while his faculty of popular experimenting was of the most delicately accurate and attractive character. He had a peculiar power of gathering about him the *élite* of the best men of the year; wherever there was a man endowed with somewhat of the true scientific spirit, he was sure to gravitate towards the laboratory; and it is an interesting fact that the great majority of Dr. Andrews's most trusted laboratory students have turned out successful men in after life.

"But, however eminent have been Dr. Andrews's services in the directions already alluded to, it is as an original scientific investigator that he has gained his principal title to an immortal place in the annals of fame. Dr. Andrews belongs to the first rank of that remarkable body of professed chemists whose researches have been more of a physical than of a chemical nature. The names of Faraday, Graham, and Regnault, at once suggest themselves in this connection; and we are quite justified in saying that in insight, accuracy, and originality, as well as in the intrinsic value of their results, Dr. Andrews's investigations will bear comparison with the very best work of these great men. We cannot here attempt to give more than a very brief notice of the results of some of the more important of Dr. Andrews's papers. The complete list will be found in that invaluable work "The Royal Society Catalogue of Scientific Papers," to which all men of science are under the deepest obligations. The most important of his earlier investigations is a brilliant series of determinations of the heat of combination of different classes of substances. Considering the difficulties of this inquiry, as shown by the preposterous results which have sometimes been given even by able experimenters, the simplicity of Dr. Andrews's methods and the recognised accuracy of his results form a striking tribute to his care and skill. The results are not only of high theoretical value as regards the constitution of matter, but also of great importance for practical determinations of the electromotive force of various voltaic combinations. Next we have his grand researches on ozone, a remarkable body first distinctly recognised by Schönbein, whose nature was long a puzzle to chemists. It was reserved for Dr. Andrews to show (1) that ozone, from whatever source derived, is one and the same body; (2) that it is an allotropic form of oxygen. Before he cleared up these points it was generally supposed by chemists that there were different kinds of ozone, and that one of them, prepared by electrolysis, was a teroxide of hydrogen. In a second research Dr. Andrews traced the volumetric changes which occur in the formation of ozone from pure oxygen by the electric discharge—where it has been long known under the name of 'the smell of lightning'—and gave a number of similar and very remarkable volumetric changes observed in other gases, simple as well as compound, produced under the same experimental conditions. He showed that the chemical activity of chlorine could be greatly increased, just as that of oxogen was, by electric discharges. This question has again only very recently been reopened by a Continental chemist, who maintains that chlorine is not an element, but a compound body. The most recent of Dr. Andrews's grand contributions to science is his classical research into the 'Continuity of the Liquid and Gaseous States of Matter.' By means of a very simple but exquisite apparatus (prepared for him under his own directions by our very skilful townsman, Mr. Cumine), he showed that it was possible to convert a gas such as carbonic acid into a liquid, or the liquid into the gas, *without any discontinuity whatever*. In fact, a spectator may watch the body throughout the process, assure himself that it is gas at starting, and that it is liquid at last, and yet not be able to state *when* the change took place. From the scientific point of view, this phenomenon is best described by the use of Dr. Andrews's discovery of the 'critical point,' as it is called. For every gas or vapour there is a special temperature called its critical point, which is such that *only when the temperature of the gas or vapour is under that point can it exist in presence of the liquid;* so that the portion liquefied can be distinguished from the

rest. By these experiments Dr. Andrews cleared up the whole question of the liquefaction of gases by the separate or combined actions of cold and pressure. It is not too much to say that all the essential particulars as to apparatus and mode of working, by which two years ago the liquefaction of oxygen, and even of hydrogen, was effected simultaneously in France and in Switzerland, are to be found in Dr. Andrews's papers. It is to be regretted that the state of his health did not enable him to reap for himself (as he unquestionably would have done) this striking result of his beautiful investigations. But, after all, he has the credit of Adams or Leverrier, he pointed out how and where, with *certainty*, to find the hitherto unknown; and his glory is none the less that a Challis and a Galle, better provided with the requisite instrumental means, actually obtained the result. The mere fact of the liquefaction of oxygen, or the solidification of hydrogen, though very important in itself, is only one legitimate and inevitable consequence of Dr. Andrews's previous results; but it is vastly more easy of apprehension by the general public. But in the eye of science the demonstration that it is possible for matter to be made to pass by continuous stages from the gaseous to the liquid conditions forms one of the very greatest discoveries of even the nineteenth century.

"Such is the man whom, for the last half-century, we have had unostentatiously dwelling among us, prosecuting the labours that are only possible to the most exalted intellects of our race. Now that he goes into comparative retirement, there will be surely some means adopted of recognising in a permanent form connected with the college what it owes to him and to his great reputation."

GEOGRAPHICAL NOTES

WE learn from Oran that the French officers of the Staff in Algeria perceived for the first time on September 9 the electric light from the Spanish station of Tetica, at a distance of 272 kilometres. Commandant Perrier, director of the Algerian Survey, was enabled to measure one angle of the triangle, and the other having been measured from the Algerian station on the mountains, the operation may be considered as having been quite completed, and the junction of the Algerian network with the European triangulation an accomplished fact.

AT the meeting of the International Geodetical Association at Geneva no delegates are reported as having been sent from Sweden, Norway, Denmark, Netherlands, England, or Turkey. France, who resisted during the lifetime of Leverrier, sent MM. Charles Sainte Claire-Deville, Faye, and Yvon Villarceau. Not only was Germany represented by Professors Peters and Rhumkers, but Saxony by M. Bruhns, and Bavaria by M. Baurnfeind. Spain sent General Ibanez, Belgium Col. Adams, Russia General Forsch, Austria Prof. Oppolzer, Italy General Mayo, Prof. Respighi, Col. Ferrera, and Major Maggia; Switzerland had two representatives, Professors Hirsch and Plantamour, the head of the Geneva Observatory. The session was inaugurated by reading the report by M. Deville on experiments made by himself and M. Mascart, the director of the Central Bureau of French Meteorology, for the construction of the irido-platinum international metre.

M. TYAGHIN, an officer of the Russian Navy, who went in July of last year to Novaya Zemlya with his wife, a child, and three servants to winter at the life-station organised on the island, has just returned to Archangelse. All are well, and the little family has been increased by a new-born child. The winter was not severe, the greatest cold having been only $-29°\cdot1$ Celsius; and on August 1, when M. Tyaghin left Novaya Zemlya, the thermometer rose as high as 16°. The five Samoyede families who were sent to the same station are well, but one old man of more than sixty years and two others died from scurvy, and M. Tyaghin explains their death by the circumstance that they never went out of their dwelling and did not follow his recommendations. The hunting was good throughout the winter.

THE Russian Ministries of War and of Public Communications had resolved to send this year no less than three expeditions for the exploration of the old bed of the Amu-darya, and for researches as to the possibility of a water-communication between this river and the Caspian. The troubles in the Turcoman steppes hindered the starting of two of the expeditions which were to explore the steppes between Khiva and Krasnovodsk, and their departure has been postponed until January next. The third expedition has already started, and it is now engaged in the exploration of the Amu Darya River, and of its delta.

M. SIBIRYAKOFF publishes in Russian papers a telegram which he has received from Capt. Glasö, who tried this summer to enter the Kara Sea, and sail to the mouth of the Yenisei, on board the steamer *Samuel Owen*. All three passages, the Matochkin, the Kara, and the Yugor Straits, were encumbered with ice, and Capt. Glasö returned on August 26 without attempting the passage around the northern extremity of Novaya Zemlya.

ON July 28 last Dr. Gerhard Rohlfs' expedition left the Oasis of Batifal, situated at some twenty-eight kilometres distance from Djalo, in order to reach the northernmost Oasis of Siren in seven days, and Istat, the principal place in the southern Oasis of Kebalo, in the Kafra Group in twelve days. Dr. Rohlfs expected to arrive at Wadai in the middle of October. This results from a letter written by his companion, Dr. Stecker, to Prof. von Hochstetter, of Vienna. Another letter, written to a friend at Prague, states that Dr. Rohlfs will leave the expedition either at Wadai or even at Kafra, and return to Europe. Dr. Stecker will then continue the journey alone. It will be remembered that Dr. Rohlfs had already resolved to resign the leadership, but on second thoughts decided to remain. His final resignation is much to be regretted.

THE Imperial Geographical Society of St. Petersburg intends to form a connection with other institutions of the Russian Empire with a view of editing, in conjunction with them, a general description of Siberia with maps and plans, upon the occasion of the approaching tercentenary of the occupation of Siberia by the Russians. The Society will undertake the purely geographical part of the work and will also publish a bibliographical review of all other works on Siberia hitherto published.

THE International Society for the exploration of Equatorial Africa is very busy opening commercial relations between the settlements at the mouth of the Congo River and the interior. A few weeks ago the steamer *Barga* left Antwerp with European merchandise for this purpose. The steamer also takes out three small steam launches, a small steamer which will hold about thirty passengers, and three large goods-barges. By means of these the lower cataracts and rapids of the Congo will doubtless soon be reached. It is intended to establish stores at that point on both banks of the river. The question then will be to make a road along the river up to that point, where it again becomes navigable.

THE Imperial "Leopoldinisch-Carolinische" German Academy of Naturalists at Halle, which possesses the right of conferring doctor-diplomas, has lately bestowed this honourable distinction upon the three eminent travellers, Julius Payer, Karl Weyprecht, and Henry M. Stanley.

THE Berlin Geographical Society will celebrate the centenary of the birth of Karl Ritter, which happened on August 7, 1779, after the vacation, *i.e.* in October next.

TAILS[1]

WHAT are tails? The question seems an almost trivial one in its simplicity. Dictionaries tell us that the word "tail" denotes certain parts of animals, and also the hindermost or lowermost portion of anything. We speak habitually of the "tail of a coat," the "tail end of a crowd," the "tail of a kite," and of "pig-tails," as well as "tails of pigs." Evidently all these appellations are in use from the perception of more or less close analogies between the various things thus spoken of and certain things which every one who speaks English must call a tail—something which is unmistakably, truly, and properly a tail.

Such a thing, for example, is the tail of a cat or of a dog.

Let us, then, examine such an object and see what a typical tail is, and afterwards compare therewith other structures more or less closely or remotely resembling it.

But in order to understand that part of a cat which is called its "tail," we must understand those other parts which are not its tail, since we can never know any one thing whatever except by knowing other things from which such one thing is distinguished. We could not know "white," if everything that we saw was always of that colour.

The frame of a cat consists of a head, a trunk, limbs, and a tail.

Let us first look at its trunk. It consists of a solid fleshy wall (partly strengthened by bones—the ribs, breastbone and backbone) containing a cavity within; this cavity within the trunk is called the body-cavity. Inside this body-cavity are a variety of parts (*viscera*), such as the heart and its great blood-vessels, the liver, &c., and the cavity is traversed by a long, much-coiled tube called the alimentary canal, *i.e.*, swallow, stomach, intestines, &c.). Passing along the upper or dorsal side of the body is the backbone just mentioned. This consists of a complex chain of neatly articulated bones, each of which is called a *vertebra*, and the whole series of such bones form the *vertebral column*, *spine*, or *spinal column*, which are other names for the backbone. Now observe: Each vertebra of the trunk is in the form of an irregular ring. Therefore, as these rings come naturally in a series one behind the other, they together form a canal. This canal is called the *neural canal*, because it contains the central part of the nervous system, or *neural axis*, also *improperly* called the *spinal marrow*.

Thus, altogether, the cat's trunk consists of a solid case containing a body-cavity (within which lie the viscera), while the dorsal region of the case is traversed by the backbone or vertebral column, forming a canal along which runs the spinal marrow.

The neck is but the anterior prolongation of the trunk.

The cat's head is much more bony in proportion than is the trunk, and consists partly of a solid box, which holds the brain and shelters the ears and eyes and partly of a face and jaws, which latter bound the mouth. The brain case has a large hole behind, which matches with those which exist in each trunk vertebra, and through this hole the neural canal is continued on into the hollow of the skull, which is its expanded front end. Thus, altogether, the cat's head is in certain respects like its trunk. It is traversed by the alimentary tube, which opens at the mouth, and it has its dorsal part formed by the much-expanded neural canal (the skull-cavity) which contains the brain, or much-expanded anterior end of the neural axis.

The cat's limbs are very different in structure from the head and trunk. No body-cavity is contained in them, nor does the body-cavity of the trunk extend into any limb, nor again is any limb traversed by any part of the alimentary canal. Each limb has a solid bony support within it, but this support (the skeleton of each limb) is no part of the vertebral column, nor is it composed of any sort of vertebræ, but consists of a definite number of longer or shorter bones which are related to the support of the body or to its progression in walking, running, jumping, &c. These limb-bones do not contain any canal (as the backbone does), nor do they shelter any continuation sideways from the central part of the nervous system.

We now come to the tail, and if we examine it, we shall see that, to a certain extent, it partakes of the natures both of the trunk and of the limbs. It is like the limbs in that it is solid, that it contains no body-cavity, and is not traversed by the alimentary canal.

It is like the trunk in that it contains a prolongation of the vertebral column, and of the neural canal. In the head, we saw that the neural canal expanded, it receives its anterior enlarged termination—*the brain*. In the tail the neural canal contracts, and soon ceases, as it incloses the progressively diminishing posterior end of the neural axis—the termination backwards of the spinal marrow.

Let us examine the bones which form the cat's tail a little closely. They are about a score in number. The first seven or eight are all in the form of rings of bone, but behind these the vertebræ become merely more or less elongated solid bony cylinders, which get gradually smaller till they become mere rudiments of vertebræ. Beneath the vertebræ run blood-vessels, and on all sides are muscles which serve to bend the tail in all directions.

Such is the structure of the tail in this animal, *its use* (or "*function*") is not very important. Cats can live very well without their tails, and the well-known Isle of Man variety—the Manx cat—has scarcely more visible tail than we have ourselves. Yet the cat's tail no doubt aids to a certain extent in maintaining the balance of the body in the animal's various motions, and especially perhaps in climbing. Everybody has noticed the lateral undulations of the end of the tail of a cat which is watching a mouse, and it is curious to note how the wagging of the tail in the cat and the dog respectively, accompany very different emotions.

The gesture language of these two animals as expressed by the motion of their tails, and, indeed, by various other motions, is exceedingly different.

The structural characters which have been noticed concerning the cat's tail are substantially similar in all other beasts. In all, the tail is formed by a prolongation of the back bone (with more or less of neural canal), but has no body-cavity, and is not traversed by the alimentary canal.

But, although the essential structure in all beasts is similar, there are certain subordinate differences which merit our attention in the form of the tail in different beasts.

Dogs and cats belong to a great group of flesh-eating beasts, called, from their predominant mode of feeding, "*carnivora.*" Bears, weasels, badgers, civet-cats, seals, and sea-bears, also belong to this group.

If you enter the small mammalia house you may see a beast allied to the badger and weasel, called the *kinkajou.* This animal is an inhabitant of Brazil, and its tail bears a relation to the region it inhabits.

The animal lives in trees which it roams over in search of small animals on which it preys, such as birds' eggs and bees' nests, and these nests its sharp strong claws can tear, while it has an extremely long tongue, capable of being thrust into the cells and extracting the honey. But its tail, which is very long, is specially modified to assist it in its mode of life. The end of the tail is curled round, and is capable of strongly grasping any object about which it may be twined.

This kind of tail is called a "*prehensile tail,*" and acts as a fifth grasping organ, in addition to the two hands and the two feet.

It is in this prehensile character that the kinkajou's

[1] A Davis lecture recently delivered at the Zoological Gardens by Prof. St. George Mivart, F.R.S., V.P.Z.S.

tail, as I said, bears a relation to the region it inhabits. For Brazil consists mainly of an enormously extended forest, South America presenting us with the main forest region of the world. Consequently, the animals inhabiting this region must be fitted for an exceptionally arboreal life. The primeval forest exhibits as it were a world borne aloft upon enormous pillars.

Walking in such a forest, one wanders in obscurity amongst enormous lofty trunks, at the summits of which is a mass of entangled foliage high over head, and shutting out almost completely the sun's rays from below. It is in this upper world that most of the forest animals live, and such conditions necessitate in them special modifications of structure, of one kind or another, and the prehensile character of the kinkajou's tail is one such modification. I do not mean to say that animals with prehensile tails are not found elsewhere; we shall shortly see that they are. Neither do I mean to say that this particular character is universal amongst forest-living beasts of South America. The sloths, for example, are notoriously and exclusively forest-dwellers, and they are most exceptionally modified to suit their dwelling-place; but the mode of modification by which they are suited to a forest home is of quite another kind; it is one, however, which it would be beside our purpose to enter upon to-day. Nevertheless, this particular character of tail does crop up amongst South American beasts remarkably. Thus, for example, let us consider the great order of monkeys. Monkeys are scattered over almost all the warmest parts of the earth save the West Indies, Madagascar, New Guinea, and Australia. A great variety of species are found in Africa, India, and the Indian Archipelago, and many of them have long tails; but not one kind of monkey in Asia or Africa has a prehensile tail. In South America, however, we find apes (such as the *Howling Monkeys* and the *Spider Monkeys*) which have tails most perfectly prehensile, for they are naked beneath towards the tip, and on that account can be applied more closely and firmly to any object grasped more firmly by the tail than they could be grasped were the tail entirely hairy. The tail, indeed, is not only capable of alone supporting the weight of the body, but even of seizing a small movable object, and bringing it in as a hand would do to the mouth.

Monkeys may have long or they may have short tails, and there are some which have no visible tails at all. This is the case with the only European ape—the one which inhabits the Rock of Gibraltar. It is also the case

FIG. 1.—Caudal vertebræ of *Inuus*.

with the Gibbons, or long-armed apes (which we have had living here from time to time, and some of which are so remarkable for their powers of voice). It is also the case with the orang-outang, the chimpanzee, and gorilla, which are as devoid of tails as we are. But are they, and are *we*, really devoid of tails? Practically, of course, we are so, but nevertheless the spinal column has a rudimentary continuation formed of a few very imperfect vertebræ—not sufficiently elongated to form an external projection, so that in the human skeleton a minute tail is to be seen, though none is visible in the unmutilated adult body. In the earliest stages of our existence, however, there is for a short time a real tail of considerable relative extent, but in the development of the body it becomes stationary, so as rapidly to become altogether overshadowed and hidden.

FIG. 2.—The Coccyx. At its upper end are the two prezygapophyses.

As I have said, Madagascar is not inhabited by monkeys, but it is inhabited, instead, by creatures called lemurs, with long fox-like muzzles, of which several are now living in our monkey-house. There also there was lately living another Madagascar creature (a near ally of the lemur) called *Chierogaleus*, and some of these creatures are said to present an interesting peculiarity in the tail.

Although Madagascar is a hot country, yet some of the animals inhabiting it fall into a profound sleep, or torpor, during the dry season, just as our own hedgehog falls into a profound torpor during the winter. Now some of these little lemur-like animals, called *Cheirogalei*, accumulate during a part of the year a great quantity of fat in the tail, which, in consequence, appears much swollen and enlarged. Upon this fat the animals appear to subsist during the other part of the year—not, of course, that they eat it, but that it becomes gradually absorbed, so that as the year comes round, the tail becomes as small again as it was when the fattening process began.

I have shown you how rudimentary the tail is in ourselves. There are many other animals, however, in which there is no tail. In certain bats the bones of the tail are firmly united at their hinder end with the bones of the hip-girdle or pelvis, so that at first sight there seems to be even less tail in them than in ourselves.

Very different is the condition of the tail in other bats, such as in all those which fly about in summer evenings in England.

These creatures fly by means of wings which are hands with fingers enormously long and exceedingly slender, and tied together by skin, their hands being web-fingered as a duck's foot is web-toed. But not only does this skin extend between the long fingers, it also extends from the hands to the sides of the body and legs, forming an enormous membranous wing on each side of the body.

The tail is similarly conditioned. A membrane extends inwards from the whole length of the inside of each leg, and joins the adjacent side of the tail, which is thus held in a membrane called *inter-femoral*, from its situation. In the bat the tail serves as a rudder in flying, but it also performs another function, for by the bending forwards of the tail and the inter-femoral membrane it serves as a cradle in which the infant bat is held on its first appearance in the world.

An "inter-femoral membrane" extending from the legs to the tail between them, also exists in an animal of a widely different form and nature, namely, in the seal.

The two hind legs of the seal are of no use whatever to the animal for progression on land, and the seal thus differs from the sea-bear. The hind-legs of the seal are kept extended out backwards, much in the position in which a man holds his legs when he swims. But they act in quite a different way in swimming from the way our legs act. Being united by an inter-femoral membrane with the tail, the whole mass of the legs and tail together form a sort of fin, which strikes the water as a whole, and so propels the body of the animal along in the water.

Very different is the tail of the whale, porpoise, or such a creature as the manatee or the dugong. None of these creatures have hind-legs at all, or but the merest rudiment

of such in the shape of a few very small bones buried in the flesh. On the other hand, the tail is enormous in bulk, and expands outwards on each side at its hinder end, but in this expansion there are no limb-bones whatever; it is only a cutaneous expansion. This expansion extends horizontally in these animals. Why is this?

FIG. 3.—Dugong.

Fishes, such as the cod, perch, salmon, shark, &c., have the ends of their tails expanded vertically, not horizontally, and it is very evident why.

Fishes swim by bending the tail from side to side and striking the water laterally, as those in any aquarium will show us. They also breathe by the water which flows over their gills.

Whales and porpoises are not fishes, but they are (as is also the manatee and the dugong) aquatic beasts, and they breathe air by lungs as other beasts do. This is the key to the difference in their tails, that is, the horizontal expansion of the hinder end. They require to bring their heads pretty often to the surface to breathe, and the horizontally expanded tail is well fitted to help them in so ascending by its downward blows.

But the tail of the whale or porpoise, strange to say, affords perhaps a partial explanation of the form of the head in these animals. For whales and porpoises are quite remarkable for the large size of their brains. Now the brain is commonly supposed—and in many cases with much reason—to be related to the powers of sensation and imagination which animals possess. Yet it is impossible to think that these marine creatures have any need for exceptionally acute or powerful minds.

But brain stuff is known to be related to motion, no less than to feeling and imagination. Unless our muscles were duly stimulated by nerves and by the brain and spinal cord, they would not act. It may well be then that these animals need all their brains to supply enough nervous energy for the incessant muscular exertion which their habit of life renders necessary in the medium they inhabit. But this explanation alone will not do, for fishes have very small brains. The difference is perhaps due to the fact that whales and porpoises need to maintain a high body temperature, while fishes are cold-blooded and brain stuff is needed to maintain bodily heat no less than for sensation and motion.

The tails of beasts are generally like their bodies, covered with hair. The rat and mouse and certain opossums offer exceptions in their naked, scaly looking tails.

FIG. 4.--The Pangolin (*Manis*).

One animal from Africa, a creature much like a flying squirrel (*Anomalurus*) presents (as its name implies) a very exceptional condition of tail. It is really scaly in part, for underneath it, at a little distance from its root, it is furnished with horny overlapping scales. Such scales are yet more developed in another beast—the manis or pangolin—but then in this latter animal the whole body and limbs are thus invested and not part of the tail only.

The animal renowned for its curious naked tail—flattened out like a trowel—is the beaver. As to the use of this animal's tail our experienced superintendent, Mr. Bartlett (who is so acute and accurate an observer of animals' habits) assures me that he has often watched beavers when at work building with mud in snow, but in no instance has he seen them make use of the tail as a trowel as has so often been alleged. But the beaver has great *power* in its tail, not only as an organ used in swimming but as a means of sounding an alarm to its comrades. On the approach of an enemy the beaver strikes the surface of the water with its flat tail with such force that it can be heard, on a still night, half a mile off. Upon hearing this signal all the beavers in the neighbourhood quickly dive under the water.

The beavers which still linger in European rivers have now ceased to construct dams as do their American fellows. It is an interesting fact, however, that they still retained this habit in Europe down to the time of Albertus Magnus, who of course knew nothing of the habits of the beavers of the then undiscovered America.

In the Zoological Gardens are creatures which are provided with exceptionally powerful tails—for land animals—I mean the kangaroos. These creatures make use of their tails not only sometimes to carry grass, and to a certain extent in their long jumps, but constantly when sitting with the fore part of the body raised, and in this position they often raise themselves high up on their extended hind legs and on their tail as on a strong tripod, at which time they have a most comic appearance.

And this brings me to speak of another matter. As I have said the sloths are fitted to live in trees not by any peculiar development of tail, but in other ways. Certain gigantic extinct allies of sloths, however, were fitted for a forest life and to live entirely on the foliage of trees by their tails. Such extinct beasts were the *Mylodon* and *Megatherium*, creatures equalling or exceeding the rhinoceros in bulk.

The modification of tail specially adapted for forest life with which we have as yet met, has been a *prehensile tail*. This we have seen in the kinkajou and in howling and spider monkeys. Many other beasts, how-

ever, of very different kinds are provided with prehensile tails.

Amongst others may be mentioned tree-porcupines, certain opossums, and a small ant-eater. All these animals live on trees. But the mylodon and megatherium—though forest animals living in all probability exclusively on the foliage of trees, were far too bulky to climb them, or to be supported by their branches. They appear to have fed thus: raising themselves on their hind legs and tail (as on a tripod—like the kangaroos) they embraced trees with their powerful arms, and swaying them to and fro, gradually prostrated them in order to feed upon their leaves. It has been objected to this view of their probable habits, that if they acted in this way they must often get their heads broken. Well, strange to say, the heads of some fossils *have* had their heads broken and healed again, and their skull was specially constructed so as to obviate to a considerable extent the danger of fatal consequences ensuing from accidents of that kind.

The tails of some beasts are, as I have said, exceptionally naked. The tails of others, however, are exceptionally hairy. Such is the case with the horse, which is called "long-tailed" when the tail is adorned with a clothing of very long hairs.

(*To be continued.*)

OUR ASTRONOMICAL COLUMN

BIELA'S COMET IN 1852.—In view of the probable approach to the earth's orbit of the two heads of Biela's comet in the present year, it is not without interest to recall the circumstances under which these bodies were last observed in the autumn of 1852. As soon as the calculated place of what was assumed to be the principal comet of 1846, according to Santini, was sufficiently removed from the sun's place to afford a chance of discovery, a search was commenced at several European observatories, notably by Secchi, at the Observatory of the Collegio Romano at Rome. The comet was not found in its computed position, and the cause of this is now known to have been the abandonment by Santini of his old semi-axis major, founded originally upon Damoiseau's calculation of the perturbations of mean motion between the appearances in 1805-6 and 1826, and the observations of those years and the substitution of a value deduced by Plantamour from the observations in 1845-46; had the original semi-axis been retained the comet would have been readily found by means of Santini's computations. Extending the limits of the search, therefore, Secchi detected a faint comet on the morning of August 26, 1852, some 6° from the calculated place, which Prof. Peters of Altona immediately pointed out as probably one portion of Biela's comet, from the rate and direction of its motion, as, indeed, it proved to be. (In *Memorie dell' Osservatorio del Collegio Romano, anni* 1852-55, the discovery is dated, by a misprint, August 16, civil reckoning, the first observation was made on August 25, at 16h. 14m. M.T.) This object was observed on several subsequent mornings, and on September 16 Secchi found the other head of the comet, following that previously observed about two minutes of time, and about half a degree to the south. With the great refractor at Pulkowa, M. Otto Struve found Secchi's comet of August 26, on September 18 (astronomical), or immediately after the notice reached him, and two mornings later, he observed both heads. Mr. James Breen, to whom Prof. Challis had intrusted the Northumberland equatorial at Cambridge for a search for the comet, found one portion of it on September 8, and observed it further on September 16 and 21. At Berlin one head was detected on September 17, and reobserved on September 22. M. Otto Struve, in his account of the Pulkowa observations, calls that head of the comet which was first observed by Secchi on August 25, A, and that found on September 15, using now astronomical dates, he calls B; the latter was the north-preceding comet, the former the south-following one. A discussion of the observations of both heads, twenty-two in number, showed that those at Cambridge referred to A on all three mornings, and those at Berlin to B; both nuclei were observed at Rome on September 19 and 20, and at Pulkowa on September 20, 23, and 25. The appearance of the two portions of the comet is best described in M. Otto Struve's memoir, which is also accompanied by two admirably executed drawings, depicting their relative aspect on September 20 and 25, B on September 18 was at least 30″ in diameter, with sensible brightening in the centre, but no decided nucleus, and the light of the comet was about equal to that of a star of Argelander's ninth magnitude. On September 20 A was easily seen with the finder of the large refractor, both heads were of about equal brightness, B might be a little the brighter, and exhibited a distinct nucleus; the nucleus of A was not so distinct as that of B, and there was a greater brightness of the nebulosity, as well as an extension of it in the direction of B; the apparent diameters about 1′ and 40″; the diameter of B, which was circular, was estimated 40″. On September 23 A was notably fainter than B, and without nucleus; the lengthened form of A was only seen with difficulty, but the sky was not quite transparent. On September 25 there was a remarkable change as compared with the relative appearance of the two heads five days before; A was materially fainter than B; the latter was very distinct in the finder, while the place of the former was hardly suspected; diameter of A about 30″, that of B from 50″ to 60″. A was round, B slightly oblong; the brightest part of A was not in the centre of the nebulosity, but in the direction of B, and the nucleus of B was in the opposite direction to A, the brightest part of the nebulosity unequally distributed about the nucleus of B being turned away from A; the position-angle of this direction was 286°. On September 28, the last day of observation, the moonlight was strong, and B only was seen with difficulty. We give these details, not remembering to have seen them reproduced in this country; but the description fails to convey the impression made by comparing M. Otto Struve's drawings of September 20 and 25; were it not that we know to the contrary, it might almost be inferred therefrom that one portion of the comet had revolved round the other to the extent of 180°; their relative appearance had been wholly interchanged, and it will be remembered that about February 12, 1846, the secondary comet much exceeded in brightness the primary one, though this continued only three or four days, when the latter resumed its previous decided superiority. There was thus, as M. Struve remarks, the same interchange of brightness between the two nuclei at both appearances, and this he is inclined to attribute to a mutual action. It may, however, be remarked that the distance between them in 1852 was, according to Hubbard, 0·0193, or about 1,750,000 miles, which seems to militate against such an explanation, and rather to induce an idea of action inherent in the separate comets, or of influence exercised upon them through their approach to the sun. At M. Struve's observations of September 20, using Hubbard's elements, we find the distance of A from the earth was 1·492, and that of B, 1·483; while on September 25, the distance of A was 1·525, and of B, 1·511; so that there was no marked change of distance between the dates of his drawings.

VARIABLE STARS.—The following are Greenwich mean times of geocentric minima of *Algol* observable in this country during the last three months of the present year:—

		h. m.			h. m.			h. m.
Oct.	6 ...	15 57·6	Nov.	1 ...	11 16·1	Dec.	8 ...	17 52·1
	9 ...	12 46·2		3 ...	8 4·9		11 ...	14 41·2
	12 ...	9 34·9		18 ...	16 9·2		14 ...	11 30·3
	15 ...	6 23·6		21 ...	12 58·2		17 ...	8 19·4
	29 ...	14 27·3		24 ...	9 47·1		20 ...	5 8·5
				27 ...	6 36·1		31 ...	16 25·0

Minima of S Cancri occur on

	h. m.		h. m.
Oct. 7	9 17·6	Dec. 3	6 56·3
26	8 30·5	12	18 33·0
Nov. 14	7 43·3	22	6 9·9
		31	17 46·3

R Leporis will be at a maximum on October 3, and χ Cygni at a minimum on December 6 according to Schönfeld's elements, but the average period of late years, 406 days added to Schmidt's last well-determined epoch of minimum, October 11, 1878, would fix the next minimum on November 21; observations of this star are much to be desired, owing to the irregularities in the period which have been recently evident; the star is a little brighter than 13m. at minimum.

The star observed six times at Bonn in 1863 in R.A. 22h. 28m. 16·9s., Decl. $-8^\circ\ 21'\ 19''$ for 1855·0 is variable from 9m. to below 13·5m., and though long notified as a variable star, appears to have been little observed. It was invisible on November 9, 1874. Cooper estimated it 9m. on October 27, 1848, and it was equally bright in August, 1855. This object is not in Schönfeld's catalogue of 1875.

THE NEW MINOR PLANETS.—Names continue to be assigned to the newer discoveries in this group, though they can hardly be said to be invariably euphonious, at least to English ears. The last circular of the *Berliner Astronomisches Jahrbuch* states that the following selection has been made by the Berlin astronomers at the request of the discoverer, Herr Palisa, of Pola: for No. 192, *Nausikaa;* No. 195, *Eurykleia;* No. 197, *Arete;* and for No. 201, *Penelope.*

THE OUTER SATELLITE OF MARS.—The satellite *Deimos* was observed by Mr. A. A. Common, of Ealing, on the morning of September 22, or three weeks earlier than Prof. Asaph Hall expected that it would be observable with the Washington 26-inch refractor. Mr. Common's angle of position, measured with his new 36-inch silver-on-glass reflector, differs only $+1^\circ{\cdot}8$ from that assigned by Prof. Hall's elements.

NOTES

WE regret to have to announce the death of Mrs. Norman Lockyer, an occasional contributor to this journal and translator of several French works on popular science. Her husband's scientific work for the last eleven years owes whatever it may possess of merit to her constant interest, encouragement, and assistance. Her untimely death will be a shock to many men of science in many lands to whom she was personally known.

IT will interest many of our readers to learn that Dr. William Jack, who has been an occasional contributor to NATURE, and is well known to most of those connected with it, has been unanimously elected to the chair of Mathematics in Glasgow University, recently vacated by Prof. Blackburn.

BARON FERDINAND VON MÜLLER, Government botanist of Victoria, has been rewarded for his Colonial services as a naturalist with the Knight Commandership of the Order of St. Michael and St. George.

THE death, on the 13th inst., is announced, of Mr. W. Wilson Saunders, F.R.S.

THE 110th anniversary of the birthday of Alexander von Humboldt was publicly celebrated by the Society of Cosmophiles at Leipzig on the 14th inst. A festival address was delivered by the secretary of the Society, Herr E. Haynel.

AT the Berlin meeting of the German Astronomical Society on September 5-8 last the series of scientific communications was opened by Dr. Förster, who minutely described the innovations recently made at the Berlin Observatory, which he subsequently invited the meeting to inspect. Prof. Bruhns, of Leipzig, spoke on the progress made in calculating the orbits of comets, Prof. Gylden, of Stockholm, pointing out a shorter method in these calculations. Prof. Winnecke then gave a description of the new Strassburg Observatory, and was followed by Dr. Drechsler, of Dresden, who made a communication on the collections belonging to the Royal Mathematical Saloon of Dresden. The last paper was by Prof. Schaffarick on variable stars. At the subsequent inspection of the Berlin Observatory the excellent arrangements to prevent damage to the instruments from variations in temperature were particularly admired. Great admiration was also elicited by the Astro-Physical Observatory at the Telegraphenberg, near Potsdam. The Society will meet again at Strassburg in 1881.

WE have already, in our "Notes," chronicled the "inauguration" of the Water Supply Exhibition at the Alexandra Palace by the Lord Mayor, on August 14. The exhibition is being held under the auspices of the committee for promoting a permanent water supply museum to be established somewhere in London, the lessees of the Palace kindly placing their exhibition court at the disposal of the committee for the purpose. The "inauguration" was fixed at a date when the exhibition was in a very rudimentary state; but as the Lord Mayor had given his patronage, and as he was leaving town on the 15th, it was felt undesirable to postpone it. The exhibition has grown slowly since then, though it is still far from coming up to the scheme as sketched out by the committee. The nature of the exhibition precludes its growing very rapidly, for the scheme does not appeal to many classes of exhibitors, and no commercial benefits are likely to accrue to contributors except in a few of the trade sections. It is understood that the Lord Mayor, accompanied by some of the provincial mayors, will visit the exhibition to-morrow (Friday), and will be entertained at lunch. This visit may help to draw attention to the effort to establish what might be made a very valuable institution.

THE statue to Arago was unveiled at Perpignan on September 20. Arago is represented as speaking and extending his arm towards the heavens. There are also three bas-reliefs. The first shows young Arago preparing for his examination at the Polytechnic School and studying without any master at the Old Perpignan fortifications. The second is the triumphant march from the Observatory to the Hotel de Ville, when Arago proclaimed the Republic in 1848; the great astronomer is leaning on Emanuel, his eldest son, now a member of the French Senate. The third relief represents Arago almost blind, sitting on his bed and composing his memoirs; Madame Langier, his niece, is writing what the great dying astronomer is dictating.

A METEOROLOGICAL station is to be established at Mont de Mignons, near Nice.

ONE feature of the last eruption of the remarkable volcano of Kilauea, in the Sandwich Islands, is the fact that the great molten lake of lava, occupying a huge caldron nearly a mile in width, and known as the "South Lake," was drawn off subterraneously, giving no warning of its movements and leaving no visible indication of its pathway or the place of its final deposit. "Other eruptions," writes Dr. Coan to Prof. Dana, in a letter dated June 20, "have blazed their way on the surface to the sea, or while on their subterranean way have rent the superincumbent beds, throwing out jets of steam or of sulphurous gases, with here and there small patches or broad areas of lava. But as yet no surface-marks of this kind reveal the silent, solemn course of this burning river. One theory is that it flowed deep in subterranean fissures, and finally disembogued far out at sea. Our ocean was much disturbed during those days, and we had what might be

called a tidal wave of moderate magnitude." The old process of replenishment which had gone on since the last eruption in 1868, is reported to have begun again, and after another decade another disgorgement may take place.

THE Indian correspondent of the *Times* has recently referred to the terrible famine now prevailing in Cashmere, the immediate cause of which is no doubt the long-continued drought which has prevailed in the country. This drought unfortunately followed upon a snowfall in the winter and spring of 1877-78 in magnitude and duration unprecedented in Cashmere, or probably in any other country. Some interesting details of this extraordinary snowfall are given in a paper in the just-issued number of the *Journal* of the Asiatic Society of Bengal by Mr. Lydekker. Early in the month of October, 1877, snow commenced to fall in the valley and mountains of Cashmere, and from that time up to May, 1878, there seems to have been an almost incessant snowfall in the higher mountains and valleys; indeed, in places it frequently snowed without intermission for upwards of ten days at a time. At Dras, which has an elevation of 10,000 feet, Mr. Lydekker estimated the snowfall from the native account, as having been been from 30 feet to 40 feet thick. The effects of this enormous snowfall were to be seen throughout the country. At Dras the well-built travellers' bungalow, which had stood some thirty years, was entirely crushed down by the weight of the snow which fell upon it. In almost every village of the neighbouring mountains more or less of the loghouses had likewise fallen, while at Gulmarg and Sonamarg, where no attempt was made to remove the snow, almost all the huts of the European visitors were utterly broken down by it. In the higher mountains whole hillsides have been denuded of vegetation and soil by the enormous avalanches which swept down them, leaving vast gaps in the primeval forests and choking the valleys below with the *débris* of rocks and trees. As an instance of the amount of snow which must have fallen in the higher levels, Mr. Lydekker mentions the Zogi Pass, leading from Cashmere to Dras, which has an elevation of 11,300 feet. He crossed this early in August last year, and he then found that the whole of the ravine leading up to the pass from the Cashmere side was still filled with snow, which he estimated in places to be at least 150 feet thick. In ordinary seasons this road in the Zogi Pass is clear from snow some time during the month of June. As another instance of the great snowfall, Mr. Lydekker takes the valley leading from the town of Dras up to the pass separating that place from the valley of the Kishengunga River. About the middle of August almost the whole of the first-mentioned valley, at an elevation of 12,000 feet, was completely choked with snow, which in places was at least 200 feet thick. In the same district all passes over 13,000 feet were still deep in snow at the same season of the year. Mr. Lydekker gives other instances of snow lying in places in September where no snow had ever before been observed after June. As to the destruction of animal life, in the Upper Wardwan Valley large numbers of ibex were seen imbedded in snow; in one place upwards of 60 heads were counted, and in another not less than 100. The most convincing proof, however, of the havoc caused among the wild animals by the great snowfall is the fact that scarcely any ibex were seen during last summer in those portions of the Wardwan and Tilail Valleys which are ordinarily considered as sure finds. So also the red bear and the marmot were far less numerous than usual. Mr. Lydekker estimates that the destruction to animal life caused by the snow has far exceeded any slaughter which could be inflicted by sportsmen during a period of at least five or six years.

PROF. ADLER has published a paper on the excavations at Olympia from which it appears that altogether the following numbers of antiquities have been found there:—1,328 different sculptures, 7,464 bronzes, 696 inscriptions, 2,935 coins, 2,094 terra-cotta objects, and 105 different objects made of glass, horn, lead, &c.

BARON TAYLOR, the celebrated founder of a number of literary and scientific associations for assisting literary men, artists, and men of science, has died in Paris at the age of ninety. The aggregate income of the seven associations which he founded amounts to about 10,000*l*. The son of an Englishman, he was born in Brussels, and became a Frenchman by naturalisation. He made a number of explorations in Spain and Egypt—the Luxor obelisk being brought over mainly by his exertions. He was appointed a member of the French Senate by Napoleon III. in 1869, owing to which circumstance his funeral did not take place at the public expense, although a similar honour was paid to M. Claude Bernard, who had been his colleague in the Imperial Senate.

IN a recent part of the *Zeitschrift für Biologie*, Herr Carl Nörr published the results of some experiments made by him with a view of determining the power of the human ear for distinguishing different intensities of sound. The experiments were made with leaden balls, which from a measured height were dropped on to an iron plate; thus it was possible to determine the exact intensity of the sounds by means of the distances and weights of the balls. Herr Nörr made seven different series of experiments, each with a definite intensity of sound, which varied from a just perceptible one to one 500,000 times as loud. The results showed that the percentage of correct determinations made by the ear, decreased as the difference in intensity between any two sounds compared increased. When the difference in intensities remained the same, the percentage of correct determinations was the same both for loud as well as for scarcely audible sounds. A calculation of the numbers of correct determinations found by the experiments showed that the power of distinguishing the intensities of sound follows Fechner's law most closely, *i.e.*, that the measures of sensitiveness stand in the same proportion as the reciprocate values of the square roots of difference of intensities of sounds.

WE notice among the interesting communications made at the late Anthropological Congress at Moscow, a communication, by Prof. Inostrantseff, on the discovery of very numerous remains of man of the stone period, on the shores of Lake Ladoga. All these remains are accompanied by bones of *Bos primigenius*, bear, wolf, and seal, and belong to the post-glacial epoch.

THE Russian collections of stone implements at the Moscow Archæological Exhibition were very rich, and if we take into consideration that this subject was quite neglected in Russia until the last few years, we must conclude that Russia will soon become a wide field for the exploration of this period of human civilisation. The ease with which these remains are excavated, the immense quantities in which they are found, both on the shores of the northern lakes and on the banks of southern rivers, and the very good state in which the bones are preserved (as, for instance, the skull and bones discovered by Count Ouvaroff, already mentioned in NATURE), will surely much contribute to the development of these studies in Russia.

IN a recent paper on the radiometer to the Vienna Academy, Dr. Pulnj criticises Reynold's evaporation theory and Zollner's emission theory, and holds that neither evaporation nor emission can be the sole or chief cause of radiometric movements, else there should not be a decrease in the motion when a certain degree of rarefaction has been passed. It must be supposed that the reaction-force arising from any emission of particles which takes place is extremely small in comparison with the forces arising through rebound of molecules of gaseous material already present, so that the motion is exclusively or chiefly con-

ditioned by these. With this assumption the decrease of the motion is thus explained by Dr. Puluj, according to the kinetic theory of gas: With full atmospheric pressure the reaction-force aroused on the vanes is too small to overcome the resistance of friction and the air. With sufficient rarefaction it overcomes these resistances, and the motion begins. If the reaction-force, like the internal friction, decreases but very slowly with the pressure, the velocity of motion reaches, at a certain pressure, the maximum, and on further rarefaction it decreases, because not only the resistance of the air, but also the reaction-force awakened becomes smaller with the smaller number of rebounding molecules. In an absolutely vacuous space, the motion must quite cease, if no emission of particles took place from the vanes. Dr. Puluj further describes a radiometer, consisting of a fixed cross with mica vanes blackened on one side, and a very thin cylindrical glass cover. The outer vane edges were 2 mm. distant from the glass. The glass cylinder turned, on illumination, in an opposite direction to that in which the cross should turn. The object of the experiment was to prove that the movements of the radiometer could also not be explained by air currents.

PROF. KLINKERFUES, the director of the Göttingen Observatory, has taken out a patent for a new invention in telegraphy. The professor has discovered a method by which up to eight different messages may be sent simultaneously by the same wire, an apparatus at the receiving end printing the messages separately and all at the same time. The importance of this invention to telegraphy generally needs no comment.

AT Cannstatt (near Stuttgart) a horticultural exhibition will be held from the 25th till the 29th inst.

A NEW periodical devoted to aëronautics will be published at St. Petersburg from January next, under the name of *The Aëronaut* (*Vozdukhoplavatel*). Its editor will be M. Klinder.

A SHOCK of earthquake was felt at Lyons on the 9th inst. at 7 A.M. It proceeded in a south-northerly direction and lasted two seconds.

DR. KING's annual report on the Cinchona Plantations in British Sikkim for the year ending March 31 last, together with that of the Government quinologist, Mr. C. H. Wood, are extremely satisfactory, both with regard to the cultivation and extension of the most valuable species of cinchona as well as in the preparation of the cinchona febrifuge. Of red bark trees, *Cinchona succirubra*, 353,415 were planted out, namely, 24,725 to replace old plants uprooted in taking the bark crop, and 328,690 on new land. Special attention has been paid to the most valuable of all the medicinal barks, *C. calisaya*, known as the yellow bark tree. Of this kind there were in the nursery beds at the close of the year 60,000 cuttings and seedlings in the Mungpoo division and 1,000 in the Sittong division, all of which were nearly ready at the time the report was written, for transfer to the permanent plantations. The first crop of bark of this species was obtained in the Sikkim plantation during the past season, the result showing a yield of about 1,400 lbs. of dry bark. This species we are, however, informed, is very capricious in growth, and no locality with perfectly suitable climatic conditions for it has yet been found in British Sikkim. For the purpose of ascertaining correctly the conditions under which the Dutch have succeeded in growing the tree cheaply in Java, Dr. King has received authority to proceed thither. The summary of all kinds of cinchona plants planted out during the year under review shows a total of 4,028,055, of which 3,589,965 were of the red bark species. As nearly 300,000 lbs. of bark, the produce of the previous year, remained in the quinologist's hands, it was not deemed advisable to collect a larger crop than was really necessary to meet the requirements of the febrifuge factory, consequently the total crop of bark taken amounted to only 261,659 lbs. The continuous increase in the amount of febrifuge manufactured by the Government quinologist is very marked, for while in the year 1874-75 only 48 lbs. were produced, which in the following year had increased to 1,940 lbs., in the year under review no less a quantity than 7,007 lbs. were turned out, but notwithstanding this rapid development of the manufacture the increasing confidence in the efficacy of the febrifuge has raised the demand for it so much that the consumption of the past year greatly exceeded the quantity manufactured. To meet this growing demand the scale of manufacture at Mungpoo has been extended. Whether the febrifuge now so largely manufactured in India is capable of being improved by eliminating any of its constituents is a question still under the consideration of the committee appointed in 1877. It is satisfactory, however, to find that the further experience in the use of the drug during the past year has increased the confidence of the public and of the medical profession in its virtues. The question of manufacturing a superior drug which would not be exposed to the prejudices which have so long delayed the free distribution of the present febrifuge is still under the consideration of the committee before referred to. It is stated that it will probably be found advisable to manufacture at a slightly increased cost a preparation composed of the three sulphates, cinchonidine, cinchonine, and quinine in conjunction.

THE Congress of Viticulturists which took place at Coblenz on the 4th inst. will meet at Heilbronn next year, and the apicultural meeting which was held at Prague on the 7th inst. selected Cologne as a meeting place for 1880.

THE additions to the Zoological Society's Gardens during the past week include two African Sheep (*Ovis aries*) from West Africa, presented by Mr. R. B. N. Walker, C.M.Z.S.; two Ring-tailed Coatis (*Nasua rufa*) from South America, presented respectively by Mr. Chas. S. Barnes and Mr. Percy Brewis; a Common Fox (*Canis vulpes*), British, presented by Mr. Jas. Wheatley; a Caracal (*Felis caracal*), a Secretary Vulture (*Serpentarius reptilivorus*) from South Africa, presented by Dr. Holub; two Dunlins (*Tringa cinclus*), a Turnstone (*Strepsilas interpres*), a Ringed Plover (*Œgialitis hiaticula*), British, presented by Mr. Edmund A. T. Elliot; two Common Cuckoos (*Cuculus canorus*), British, presented respectively by Mrs. Bolton and Miss C. Bealey; a Turquoisine Parrakeet (*Euphema pulchella*) from New South Wales, presented by Mr. J. Fraser; a Square-spotted Snake (*Oxyrrhopus doliatus*) from South America, presented by Mr. H. Colgate; a Chacma Baboon (*Cynocephalus porcarius*), a Yellow Baboon (*Cynocephalus babouin*), an Isabelline Antelope (*Cervicapra isabellina*), a Sociable Vulture (*Vultur auricularis*), two Tawny Eagles (*Aquila nævioides*), two Cape-crowned Cranes (*Balearic regulorum*), a Stanley Crane (*Tetrapteryx paradisea*), from South America, deposited.

HISTORY AND METHODS OF PALÆONTOLOGICAL DISCOVERY[1]

II.

WHILE the Paris Basin was yielding such important results for palæontology, its geological structure was being worked out with great care. The results appeared in a volume by Cuvier and Alex. Brongniart, chiefly the work of the latter, published in 1808.[2] This was the first systematic investigation of tertiary strata. Three years later, the work was issued in a more extended form. The separate formations were here carefully distinguished by their fossils, the true importance of which for this purpose being distinctly recognized. This advance was not accepted without some opposition, and it is an

[1] An Address, delivered before the American Association for the Advancement of Science, at Saratoga, N.Y., August 28, 1879, by Prof. O. C. Marsh, President. Continued from p. 499.

[2] "Essai sur la Géographie minéralogique des Environs de Paris." 4to, 1808.

interesting fact that Jameson, who claimed for Werner the theory here put in practice, rejected its application, and wrote as follows: "To Cuvier and Brongniart we are indebted for much valuable information in their description of the country around Paris, but we must protest against the use they have made of fossil organic remains in their geognostical descriptions and investigations."[1]

William Smith (1769-1839), "the father of English geology," had previously published a "Tabular View of the British Strata." He appears to have arrived independently at essentially the same view as Werner in regard to the relative position of stratified rocks. He had determined that the order of succession was constant, and that the different formations might be identified at distant points by the fossils they contained. In his later works, "Strata identified by Organised Fossils," published in 1816-20, and "Stratigraphical System of Organised Fossils," 1817, he gave to the world results of many years of careful investigations on the secondary formations of England. In the latter work he speaks of the success of his method in determining strata by their fossils, as follows: "My original method of tracing the strata by the organised fossils imbedded therein, is thus reduced to a science not difficult to learn. Ever since the first written account of this discovery was circulated in 1799, it has been closely investigated by my scientific acquaintances in the vicinity of Bath, some of whom search the quarries of different strata in that district, with as much certainty of finding the characteristic fossils of the respective rocks, as if they were on the shelves of their cabinets."

The systematic study of fossils now attracted attention in England, also, and was prosecuted with considerable zeal, although with less important results than in France. An extensive work on this subject, by James Parkinson, entitled "Organic Remains of a Former World," was begun in 1804, and completed in three volumes in 1811. A second edition appeared in 1833. This work was far in advance of previous publications in England, and, being well illustrated, did much to make the collection and study of fossils popular. The belief in the geological effects of the deluge had not yet lost its power, although restricted now to the later deposits; for Parkinson in his later edition, wrote as follows: "Why the earth was at first so constituted that the deluge should be rendered necessary—why the earth could not have been at first stored with all those substances, and endued with all those properties which seem to have proceeded from the deluge—why so many beings were created, as it appears, for the purpose of being destroyed—are questions which I presume not to answer."

William Buckland (1784-1856), published in 1823 his celebrated "Reliquiæ Diluvianæ," in which he gave the results of his own observations in regard to the animal remains found in the caves, fissures, and alluvial gravels of England. The facts presented are of great value, and the work was long a model for similar researches. Buckland's conclusions were, that none of the human remains discovered in the caves were as old as the extinct mammals found with them, and that the deluge was universal. In speaking of fossil bones found in the Himalayan Mountains, he says: "The occurrence of these bones at such an enormous elevation in the region of eternal snow, and consequently in a spot now unfrequented by such animals as the horse and deer, can, I think, be explained only by supposing them to be of antediluvian origin, and that the carcases of the animals were drifted to their present place, and lodged in sand, by the diluvial waters.

The foundation of the "Geological Society of London," in 1807, marks an important point in the history of palæontology. To carefully collect materials for future generalisations, was the object in view, and this organisation gradually became the centre in Great Britain for those interested in geological science. The society was incorporated in 1826, and has since been the leading organisation in Europe for the advancement of the sciences within its field. The Geological Society of France, established at Paris in 1832, and the German Geological Society, founded at Berlin in 1848, have likewise contributed largely to geological investigations in these countries, and to some extent in other parts of the world. In the publications of these three societies the student of palæontology will find a mine of valuable materials for his work.[2]

The systematic study of fossil plants may be said to date from the publication of Adolphe Brongniart's "Prodrome," in 1828.[3]

[1] Translation of Cuvier's Discourse. Note K. (B.), p. 103, 1817.
[2] "Recherches sur les Poissons fossiles," 1833-45.
[3] "Prodrome d'une Histoire des Végétaux fossiles." 8vo. Paris, 1828.

This was very soon followed by his larger work, "Histoire des Végétaux fossiles," issued in 1828-48. Brongniart pursued the same method as Cuvier and Lamarck, viz.: the comparison of fossils with living forms, and his results were of great importance. In his "Tableau des Genres Végétaux fossiles," &c., published in Paris in 1849, he gives the classification and distribution of the genera of fossil plants, and traces out the historical progression of vegetable life on the globe, as he had done to a great extent in his previous works. He shows that the cryptogamic forms prevailed in the primary formations; the conifers and cycads in the secondary, and the higher forms in the tertiary, while four-fifths of living plants are exogens.

In England Lindley and Hutton published, in 1831-37, a valuable work in three volumes, entitled, "Fossil Flora of Great Britain." This work was illustrated by many accurate plates, in which the plants of the coal formation were especially represented. Henry Witham also published two works in 1831 and 1833, in which he treated especially of the internal structure of fossil plants. "Antediluvian Phytology," by Artis, was published in London in 1838. Bowerbank's "History of the Fossil Fruits and Seeds of the London Clay" appeared in 1843. Hooker's memoir "On the Vegetation of the Carboniferous Period, as compared with that of the Present Day," published in 1848, was an important contribution to the science. Bunbury, Williamson, and others, also published various papers on fossil plants. This branch of palæontology, however, attracted much less attention in England than on the Continent.

In Germany the study of fossil plants dates back to the beginning of the century. Von Schlotheim, a pupil of Werner, published in 1804 an illustrated volume on this subject. A more important work was that of Count Sternberg, issued in 1820-38, and illustrated with excellent plates. Cotta, in 1832, published a book with the title, "Die Dendrolithen," in which he gave the results of his investigations on the inner structure of fossil plants. Von Gutbier, in 1835, and Germar in 1844-53, described and figured the plants of two important localities in Germany. Corda's "Beiträge zur Flora der Vorwelt," issued at Prague in 1845, was essentially a continuation of the work of Sternberg. Unger's "Chloris protogæa," 1841-45, "Genera et Species Plantarum Fossilium," 1850, and his larger work, published in 1852, are all standard authorities. In the latter the theory of descent is applied to the vegetable world. Schimper and Mougeot's "Monograph on the Fossil Plants of the Vosges," 1845, was well illustrated, and contained noteworthy results.

Göppert, in 1836, published a valuable memoir entitled "Systema Filicum Fossilium," in which he made known the results of his study of fossil ferns. In the same year this botanist began a series of experiments, in which he attempted to imitate the process of fossilisation, as found in nature. He steeped various animal and vegetable substances in waters holding, some calcareous, others siliceous, and others metallic matter in solution. After a slow saturation the substances were dried and exposed to heat until the organic matters were burned. In this way Göppert successfully imitated various processes of petrifaction, and explained many things in regard to fossils that had previously been in question. His discovery of the remains of plants throughout the interior of coal did much to clear up the doubts about the formation of that substance. In 1841 Göppert published an important work, in which he compared the genera of fossil plants with those now living. In 1852, another extensive work by this author appeared, entitled "Fossile Flora des Uebergangs-Gebirges."

Andræ, Braun, Dunker, Ettingshausen, Geinitz, and Goldenberg, all made notable contributions to fossil botany in Germany, during the period we are now considering.

The systematic study of invertebrate fossils, so admirably begun by Lamarck, was continued actively in France. The tertiary shells of the Seine Valley were further investigated by Defrance, and especially by Deshayes, whose great work on this subject was begun in 1824.[1] Des Moulin's essay on "Sphérulites" in 1826, Blainville's memoir on "Belemnites" in 1827, Férussac's various memoirs on land and fresh water fossil shells, were valuable additions to the subject. A later work of great importance was D'Orbigny's "Paléontologie française," 1840-44, which described the mollusca and radiates in detail, according to formations. The other publications of this author are both numerous and valuable. Brongniart and

[1] "Description des Coquilles fossiles des Environs de Paris." 3 vols. Paris, 1824-37.

Desmarest's "Histoire naturelle des Crustaces fossiles," published in 1822, is a pioneer work on this subject. Michelins' memoir on the fossil corals of France, 1841-46, was another important contribution to palæontology. Agassiz's works on fossil echinoderms and molluscs are valuable contributions to the science. The works of d'Archiac, Coquand, Cotteau, Desor, Edwards, Haime, and de Verneuil, are likewise of permanent value.

In Italy, Bellardi, Merian, Michellotti, Phillipi, Zigno, and others, contributed important results to palæontology.

In Belgium, Bosquet, Nyst, Koninck, Ryckholt, van Beneden, and others, have all aided materially in the progress of the science.

In England, also, invertebrate fossils were studied with care, and continued progress was made. Sowerby's "Mineral Conchology of Great Britain," in six volumes, a systematic work of great value, was published in 1812-30, and soon after was translated into French and German. Its figures of fossil shells are excellent, and it is still a standard work. Miller's "Natural History of the Crinoidea," published at Bristol, in 1821, and Austin's later monograph, are valuable for reference. Brown's "Fossil Conchology of Britain and Ireland" appeared in 1839, and Brodie's "History of the Fossil Insects of England" in 1845. Phillips' illustration of the geology of Yorkshire, 1829-36, and his work on the "Palæozoic Fossils of Cornwall, Devonshire, and West Somerset," 1843, contained a great deal of original matter in regard to fossil remains. Morris's "Catalogue of British Fossils," issued in 1843, and the later edition in 1854, is most useful to the working palæontologist. The memoirs of Davidson on the Brachiopoda, Edwards, Forbes, Morris, Lycett, Sharpe, and Wood, on other Mollusca, Wright on the Echinoderms, Salter on Crustacea, Busk on Polyzoa, Jones on the Entomostraca, and Duncan and Lonsdale on Corals, are of especial value. King's volume on Permian Fossils, Mantel's various memoirs, Dixon's work on the Fossils of Sussex, 1850, and McCoy's works on Palæozoic Fossils all deserve honourable mention. Sedgwick, Murchison, and Lyell, although their greatest services were in systematic geology, each contributed important results to the kindred science of palæontology during the period we are reviewing.

In Germany, Schlotheim's treatise, "Die Petrifactenkunde," published at Gotha in 1820, did much to promote a general interest in fossils. By far the most important work issued on this subject was the "Petrifacta Germanica," by Goldfuss, in three folio volumes, 1826 to 1844, which has lost little of its value. Bronn's "Geschichte der Natur," 1841-46, was a work of great labour, and one of the most useful in the literature of this period. The author gave a list of all the known fossil species, with full reference, and also their distribution through the various formations. This gave exact data on which to base generalisations, hitherto of comparatively little value.

Among other early works of interest in this department may be mentioned Dalman's memoir on "Trilobites," 1828, and Burmeister's on the same subject, 1843. Giebel's well-known "Fauna der Vorwelt," 1847-1856, gave lists of all the fossils described up to that time, and hence is a very useful work. The "Lethæa Geognostica" by Bronn, 1834-38, and the second edition by Bronn and Roemer, 1846-56, is a comprehensive general treatise on palæontology, and the most valuable work of the kind yet published.

The researches of Ehrenberg, in regard to the lowest forms of animals and plants, threw much light on various points in palæontology, and showed the origin of extensive deposits, the nature of which had before been in doubt. Von Buch, Barrande, Beyrich, Berendt, Dunker, Geinitz, Heer, Hörnes, Klipstein, von Münster, Reuss, Roemer, Sandberger, Suess, von Hagenow, von Hauer, Zeiten, and many others, all aided in the advancement of this branch of science. Angelin, Hisinger, and Nilsson, in Scandinavia; Abich, De Waldheim, Eichwald, Keyserling, Kutorga, Nordman, Pander, Rouillier, and Volborth, in Russia; and Pusch in Poland, published important results on fossil invertebrates.

The impetus given by Cuvier to the study of vertebrate fossils extended over Europe, and great efforts were made to continue discoveries in the direction he had so admirably pointed out.

Louis Agassiz (1807-73), a pupil of Cuvier, and long an honoured member of this association, attained eminence in the study of ancient as well as of recent life. His great work on Fossil Fishes[1] deserves to rank next to Cuvier's "Ossemens fossiles." The latter contained mainly fossil mammals and reptiles, while the fishes were left without a historian till Agassiz began his investigations. His studies had admirably fitted him for the task, and his industry brought together a vast array of facts bearing on the subject. The value of this grand work consists not only in its faithful descriptions and plates, but also in the more profound results it contained. Agassiz first showed that there is a correspondence between the succession of fishes in the rocks, and their embryonal development. This is now thought to be one of the strongest points in favour of evolution, although its author interpreted the facts as bearing the other way.

Pander's memoirs on the fossil fishes of Russia form a worthy supplement to Agassiz's classic work. Brandt's publications are likewise of great value; and those of Lund, in Sweden, have an especial interest to Americans, in consequence of his researches in the caves of Brazil.

Croizet and Jobert's "Recherches sur les Ossemens fossiles du Département du Puy-de-Dôme," published in 1828, contained valuable results in regard to fossil mammals. Geoffroy St. Hilaire's researches on fossil reptiles, published in 1831, were an important advance. De Serres and De Christol's explorations in the caverns in the south of France, published between 1829 and 1839, were of much value. Schmerling's researches in the caverns of Belgium, published in 1833-36, were especially important on account of the discovery of human remains mingled with those of extinct animals. Deslongchamp's memoirs on fossil reptiles, 1835, are still of great interest. Pictet's general treatise on palæontology was a valuable addition to the literature, and has done much to encourage the study of fossils.[2] De Blainville, in his grand work, "Ostéographie," issued in 1839-56, brought together the remains of living and extinct vertebrates, forming a series of the greatest value for study. Aymard and Pomel's contributions to vertebrate palæontology are both of value. Gervais and Lartet added much to our knowledge of the subject, and Bravard and Hébert's memoirs are well known.

The brilliant discoveries of Cuvier in the Paris Basin excited great interest in England, and when it was found that the same tertiary strata existed in the south of England, careful search was made for vertebrate fossils. Remains of some of the same genera described by Cuvier were soon discovered, and other extinct animals new to science were found in various parts of the kingdom. König, to whom we owe the name *Ichthyosaurus*, and Conybeare, who gave the generic designation *Pleisosaurus*, and also *Mososaurus*, were among the earliest writers in England on fossil reptiles. The discovery of these three extinct types, and the discussion as to their nature, forms a most interesting chapter in the annals of palæontology. The discovery of the *Iguanodon*, by Mantell, and the *Megalosaurus*, by Buckland, excited still higher interest. These great reptiles differed much more widely from living forms than the mammals described by Cuvier, and the period in which they lived soon became known as the "age of reptiles." The subsequent researches of these authors added largely to the existing knowledge of various extinct forms, and their writings did much to arouse public interest in the subject.

Richard Owen, a pupil of Cuvier, followed, and brought to bear upon the subject an extensive knowledge of comparative anatomy, and a wide acquaintance with existing forms. His contributions have enriched almost every department of palæontology, and of extinct vertebrates especially he has been, since Cuvier, the chief historian. The fossil reptiles of England he has systematically described, as well as those of South Africa. The extinct struthious birds of New Zealand he has made known to science, and accurately described in extended memoirs. His researches on the fossil mammals of Great Britain, the extinct Edentates of South America, and the ancient Marsupials of Australia, each forms an important chapter in the history of our science.

The personal researches of Falconer and Cautley in the Sivalik Hills of India brought to light a marvellous vertebrate fauna of pliocene age. The remains thus secured were made known in their great work "Fauna Antiqua Sivalensis," published in London in 1845. The important contributions of Egerton to our knowledge of fossil fishes and Jardine's well-known work, "Ichnology of Annandale," also belong to this period.

The study of vertebrate fossils in Germany was prosecuted

[1] "Recherches sur les Poissons fossiles," 1833-45.

[2] "Traité élémentaire de Paléontologie," etc., Genève. 4 vols. 1844-46. Second Edition. Paris, 1853-55.

with much success during the present period. Blumenbach, the ethnologist, in several publications between 1803 and 1814, recorded valuable observations on this subject. In 1812 Sömmerring gave an excellent figure of a pterodactyle, which he named and described. Goldfuss's researches on the fossil vertebrates from the caves of Germany, published in 1820-23, made known the more important facts of that interesting fauna. His later publications on extinct amphibians and reptil s were also noteworthy. Jäger's investigations on the extinct vertebrate fauna of Würtemberg, published between 1824 and 1839, were an important advance. To Plieninger's researches in the same region, 1834-44, we owe the discovery of the first triassic mammal *Microlestes*), as well as important information in regard to labyrinthodonts. Kaup's researches on fossil mammals, 1832-41, brought to light many interesting forms, and to him we are indebted for the generic name *Dinotherium*, and excellent descriptions of the remains then known.

Count Münster's "Beiträge zur Petrifactenkunde," published 1843-46, contained several valuable papers on fossil vertebrates, and the separate papers by the same author are of interest. Andreas Wagner wrote on Pterosaurians in 1837, and later gave the first description of fossil mammals of the tertiary of Greece, 1837-40. Johannes Müller published an important illustrated work on the zeuglodonts, in 1849, and various notable memoirs, and Quenstedt, interesting descriptions of fossil reptiles, as well as other papers of value. Rütimeyer's suggestive memoirs are widely known.

Hermann von Meyer's contributions to vertebrate palæontology are by far the most important published in Germany during the period we are now considering. From 1830, his investigations on this subject were continuous for nearly forty years, and his varions publications are all of value. His "Beiträge zur Petrifactenkunde," 1831-33, contains a series of valuable memoirs. His "Palæologica," issued in 1832, includes a synopsis of the fossil vertebrates then known, with much original matter. His great work, "Zur Fauna der Vorwelt," 1845-60, includes a series of monographs invaluable to the student of vertebrate palæontology. This work, as well as his other chief publications, was illustrated with admirable plates from his own drawings. Other memoirs by this author will be found in the "Palæontographica," of which he was one of the editors. In the many volumes of this publication, which began in 1851, and is still continued, will be found much to interest the investigator in any branch of palæontology.

The Palæontographical Society of London, established in 1847, has also issued a series of volumes containing valuable memoirs in various branches of palæontology. These two publications together are a storehouse of knowledge in regard to extinct forms of animal and vegetable life.

It may be interesting here to note briefly the use of general terms in palæontology, as the gradual progress of the science was indicated to some extent in its terminology. At first, and for a long time, the name *fossil* was appropriately used for objects dug from the earth, both minerals and organic remains. The term "Oryctology," having essentially the same meaning, was also used for this branch of study. For a long period, too, the termination *ites* (λίθος, a stone) was applied to fossils to distinguish them from the corresponding living forms; as, for instance, *Ostracites*, used by Pliny. At a later date, the general name "figured stones" (*Lapides figurati*) was extensively used; and less frequently, "deluge stones" (*Lapides diluviani*). The term "organised fossils" was used to distinguish fossils from minerals, when the real difference became known, although the name *Reliquiæ* was sometimes employed. The term "petrifactions" (*Petrificata*) was defined by John Gesner in his work on fossils in 1758, and was afterwards extensively used. Palæontology is comparatively a modern term, having come into use only within the last half century. It was introduced about 1830, and soon was generally adopted in France and England; but in Germany it met with less favour, though used to some extent.

It would be interesting, too, did time permit, to trace the various opinions and superstitions, held at different times, in regard to some of the more common fossils, for example, the ammonite, or the belemnite. Of their supposed celestial origin; of their use as medicine by the ancients, and in the East to-day; of their marvellous power as charms, among the Romans, and still among the American Indians. It would be instructive, also, to compare the various views expressed by students in science, concerning some of the stranger extinct forms, for instance, the nummulites, among protozoa; the rudistes, among molluscs; or the mosasaurus, among reptiles. Dissimilar as such views were, they indicate in many cases gropings after truth—natural steps in the increase of knowledge.

The third period in the history of palæontology, which, as I have said, began with Cuvier and Lamarck at the beginning of the present century, forms a natural epoch extending through six decades. The definite characteristics of this period, as stated, were dominant during all this time, and the progress of palæontology was commensurate with that of intelligence and culture.

For the first half of this period, the marvellous discoveries in the Paris Basin excited astonishment, and absorbed attention; but the real significance and value of the facts made known by Cuvier, Lamarck, and William Smith, were not appreciated. There was still a strong tendency to regard fossils merely as interesting objects of natural history, as in the previous period, and not as the key to profounder problems in the earth's history. Many prominent geologists were still endeavouring to identify formations in different countries by their mineral characters, rather than by the fossils imbedded in them. Such names as "old red sandstone," and "new red sandstone," were given in accordance with this opinion. Humboldt, for example, attempted to compare the formations of South America and Europe by their mineral features, and doubted the value of fossils for this purpose. In 1823 he wrote as follows: "Are we justified in concluding that all formations are characterised by particular species? that the fossil shells of the chalk, the Muschelkalk, the Jura limestone, and the Alpine limestones, are all different? I think this would be pushing the induction much too far."[1] Jameson still thought minerals more important than fossils for characterising formations; while Bakewell, later yet, defines palæontology as comprising "fossil zoology and fossil botany, a knowledge of which may appear to the student as having little connection with geology."

During the later half of the third period, greater progress was made, and before its close geology was thoroughly established as a science. Let us consider for a moment what had really been accomplished up to this time.

It had now been proved beyond question that portions at least of the earth's surface had been covered many times by the sea, with alternations of fresh water and of land; that the strata thus deposited were formed in succession, the lowest of the series being the oldest; that a distinct succession of animals and plants had inhabited the earth during the different geological periods; and that the order of succession found in one part of the earth was essentially the same in all. More than 30,000 new species of extinct animals and plants had now been described. It had been found, too, that from the oldest formations to the most recent, there had been an advance in the grade of life, both animal and vegetable, the oldest forms being among the simplest, and the higher forms successively making their appearance.

It had now become clearly evident, moreover, that the fossils from the older formations were all extinct species, and that only in the most recent deposits were there remains of forms still living. The equally important fact had been established, that in several groups of both animals and plants, the extinct forms were vastly more numerous than the living; while several orders of fossil animals had no representatives in modern times. Human remains had been found mingled with those of extinct animals, but the association was regarded as an accidental one by the authorities in science; and the very recent appearance of man on the earth was not seriously questioned. Another important conclusion reached, mainly through the labours of Lyell was, that the earth had not been subjected in the past to sudden and violent revolutions; but the changes wrought had been gradual, differing in no respect from those still in progress. Strangely enough, the corollary to this proposition, that life, too, had been continuous on the earth, formed at that date no part of the common stock of knowledge.

In the physical world, the great law of "correlation of forces" had been announced, and widely accepted; but in the organic world, the dogma of the miraculous creation of each separate species still held sway, almost as completely as when Linnæus declared: "There are as many different species as there were different forms created in the beginning by the

[1] "Essai géognistique sur le Gisement des Roches," p. 41.

Infinite Being." But the dawn of a new era was already breaking, and the third period of palæontology we may consider now at an end.

Just twenty years ago, science had reached a point when the belief in "special creations" was undermined by well-established facts, slowly accumulated. The time was ripe. Many naturalists were working at the problem, convinced that evolution was the key to the present and the past. But how had Nature brought this change about? While others pondered Darwin spoke the magic word—"Natural Selection," and a new epoch in science began.

The fourth period in the history of palæontology dates from this time, and is the period of to-day. One of the main characteristics of this epoch is the belief that *all life, living and extinct, has been evolved from simple forms*. Another prominent feature is the accepted fact of *the great antiquity of the human race*. These are quite sufficient to distinguish this period sharply from those that preceded it.

The publication of Charles Darwin's work on the "Origin of Species," November, 1859, at once aroused attention, and started a revolution which has already in the short space of two decades changed the whole course of scientific thought. The theory of "Natural Selection," or, as Spencer has happily termed it, the "Survival of the Fittest," had been worked out independently by Wallace, who justly shares the honour of the discovery. We have seen that the theory of evolution was proposed and advocated by Lamarck, but he was before his time. The anonymous author of the "Vestiges of Creation," which appeared in 1844, advocated a somewhat similar theory, which attracted much attention, but the belief that species were immutable was not sensibly affected until Darwin's work appeared.

The difference between Lamarck and Darwin is essentially this: Lamarck proposed the theory of evolution; Darwin changed this into a doctrine, which is now guiding the investigation in all departments of biology. Lamarck failed to realise the importance of time, and the inter-action of life on life. Darwin, by combining these influences with those also suggested by Lamarck, has shown *how* the existing forms on the earth may have been derived from those of the past.

This revolution has influenced palæontology as extensively as any other department of science, and hence the new period we are discussing. In the last epoch species were represented independently, by parallel lines; in the present period they are indicated by dependent, branching lines. The former was the analytic, the latter is the synthetic, period. To-day the animals and plants now living are believed to be genetically connected with those of the distant past, and the palæontologist no longer deems species of the first importance, but seeks for relationships and genealogies, connecting the distant past with the present. Working in this spirit, and with such a method, the advance during the last decade has been great, and is an earnest of what is yet to come.

The progress of palæontology in Great Britain during the present period has been great, and the general interest in the science much extended. The views of Darwin soon found acceptance here. Next to his discovery of "Natural Selection," Darwin was fortunate in having so able and bold an expounder as Huxley, who was one of the first to adopt his theory and give it a vigorous support. Huxley's masterly researches have been of great benefit to all departments of biology, and his contributions to palæontology are invaluable. Among the latter his original investigations on the relations of birds and reptiles are especially noteworthy. His various memoirs on extinct reptiles, amphibians, and fishes, belong to the permanent literature of the subject. The important researches of Owen on the fossil vertebrates have been continued to the present time. He has added largely to his previous publications on the British fossil reptiles, birds, and mammals, the extinct reptiles of South Africa, and the post-tertiary birds of New Zealand. His description of the *Archæopteryx*, near the beginning of the period was a most welcome contribution.

The investigations of Egerton on fossil fishes have likewise been continued with important results. Busk, Dawkins, Flower, and Sanford have made valuable contributions to the history of fossil mammals. Bell, Günther, Hulke, Lankester, Powrie, Miall, and Seely, have made notable additions to our knowledge of reptiles, amphibians, and fishes. Among invertebrates the crustacea have been especially studied by Jones, Salter, and Woodward. Davidson, Etheridge, Lycett, Morris, Phillips, Wood, and Wright have continued their researches on molluscs; Duncan, Nicholson, and others, have investigated the extinct corals, and Binney and Carruthers the fossil plants. Numerous other important contributions have been made in Great Britain to the science during the present period.

On the Continent the advance in palæontology has, during the last two decades, been equally great. In France Gervais continued his memoirs on extinct vertebrates nearly to the present date; while Gaudry has published several volumes on the subject that are models for all students of the science. His work on the fossil animals of Greece is a perfect monograph of its kind, and his later publications are all of importance. Lartet's various works are of permanent value, and his application of palæontology to archæology brought notable results. The volume of Alphonse Milne-Edwards on fossil crustacea was a fit supplement to Brongniart and Desmarest's well-known work, while his grand memoir on fossil birds deserves to rank with the classic volumes of Cuvier. Duvernoy, Filhol, Hébert, Sauvage, and others, have also published interesting results on fossil vertebrates.

Van Beneden's researches on the fossil vertebrates of Belgium have produced results of great value. Pictet, Rütimeyer, and Wedersheim in Switzerland, Bianconi, Forsyth-Major, and Sismonda in Italy, and Nodot in Spain, have likewise published important memoirs. The extinct vertebrates have been studied in Germany by von Meyer, Carus, Fraas, Giebel, Haeckel, Haase, Hensel, Kayser, Kner, Ludwig, Peters, Portis, Maack, Salenka, Zittel, and many others; in Denmark by Reinhardt; and in Russia by Brandt and Kowalevsky.

The fossil invertebrates have been investigated with care by D'Archiac, D'Orbigny, Bayle, Fromentel, Oustalet, and others in France; Desor, Loriol, and Roux in Switzerland; Cappellini, Massalongo, Michellotti, Meneghini, and Sismonda in Italy; Barrande, Benecke, Beyrich, Dames, Dorn, Ehlers, Geinitz, Giebel, Gümbel, Feistmantel, Hagen, von Hauer, von Heyden, von Fritsch, Laube, Oppel, Quenstedt, Roemer, Schlüter, Suess, Speyer, and Zittel in Germany, and Winkler in Holland. The fossil plants have been studied in these countries by Massalongo, Saporta, Zigno, Fiedler, Goldenberg, Gehler, Heer, Goeppert, Ludwig, Schimper, Schenk, and many others.

Among the recent researches in palæontology in other regions may be mentioned those of Blanford, Feistmantel, Lydekker, and Stoliczka; in India, Haast and Hector in New Zealand, and Krefft and McCoy in Australia; all of whom have published valuable results.

Of the progress of palæontology in America I have thus far said nothing, and I need now say but little, as many of you are doubtless familiar with its main features. During the first and second periods in the history of palæontology, as I have defined them, America, for most excellent reasons, took no part. In the present century, during the third period, appear the names of Bigsby, Green, Morton, Mitchell, Rafinesque, Say, and Troost, all of whom deserve mention. More recently, the researches of Conrad, Dana, Deane, De Kay, Emmons, Gibbes, Hitchcock, Holmes, Lea, Owen, Redfield, Rogers, Shumard, Swallow, and many others, have enlarged our knowledge of the fossils of this country.

The contributions of James Hall to the invertebrate palæontology of this country form the basis of our present knowledge of the subject. The extensive labours of Meek in the same department are likewise entitled to great credit, and will form an important chapter in the history of the science. The memoirs of Billings, Gabb, Scudder, White, and Whitfield are numerous and important, and the publications of Derby, Hartt, James, Miller, Shaler, Rathburn, and Winchell, are also of value. To Dawson, Lesquereux, and Newberry, we mainly owe our present knowledge of the fossil plants of this country.

The foundation of our vertebrate palæontology was laid by Leidy, whose contributions have enriched nearly every department of the subject. The numerous publications of Cope are well known. Agassiz, Allen, Baird, Dawson, Deane, De Kay, Emmons, Gibbes, Harlan, Hitchcock, Jefferson, Lea, Le Conte, Newberry, Redfield, St. John, Warren, Whitney, Worthen, Wyman, and others, have all added to our knowledge of American fossil vertebrates. The chief results in this department of our subject, I have already laid before you on a previous occasion, and hence need not dwell upon them here.

In this rapid sketch of the history of palæontology, I have

thought it best to speak of the earlier periods more in detail, as they are less generally known, and especially as they indicate the growth of the science, and the obstacles it had to surmount. With the present work in palæontology, moreover, you are all more or less familiar, as the results are now part of the current literature. To assign every important discovery to its author would have led me far beyond my present plan. I have only endeavoured to indicate the growth of the science by citing the more prominent works that mark its progress, or illustrate the prevailing opinions and state of knowledge at the time they were written.

In considering what has been accomplished, directly or indirectly, it is well to bear in mind that without palæontology there would have been no science of geology. The latter science originated from the study of fossils, and not the reverse, as generally supposed. Palæontology, therefore, is not a mere branch of geology, but the foundation on which that science mainly rests. This fact is a sufficient excuse, if one were wanting, for noting the early opinions in regard to the changes of the earth's surface, as these changes were first studied to explain the position of fossils. The investigation of the latter first led to theories of the earth's formation, and thus to geology. When speculation replaced observation, fossils were discarded, and for a time the mineral characters of strata were thought to be the key to their position and age. For some time after this, geologists, as we have seen, apologised for using fossils to determine formations, but for the last half century their value for this purpose has been fully recognised.

The services which palæontology has rendered to botany and zoology are less easy to estimate, but are very extensive. The classification of these sciences has been rendered much more complete by the intercalation of many intermediate forms. The probable origin of various living species has been indicated by the genealogies suggested by extinct types; while our knowledge of the geographical distribution of animals and plants at the present day has been greatly improved by the facts brought out in regard to the former distribution of life on the globe.

Among the vast number of new species which have been added are the representatives of a number of new orders entirely unknown among living forms. The distribution of these extinct orders, among the different classes, is interesting, as they are mainly confined to the higher groups. Among the fossil plants, no new orders have yet been found. There are none known among the protozoa or the mollusca. The radiates have been enriched by the extinct orders of Blastoidea, Cystidea, and Edrioasterida; and the crustaceans by the Eurypterida and Trilobita. Among the vertebrates no extinct order of fossil fishes has yet been found; but the amphibians have been enlarged by the important order labyrinthodonta. The greatest additions have been among the Reptiles, where the majority of the orders are extinct. Here we have at the present date the Ichthyosauria, Sauranodontia, Plesiosauria, and Mosasauria among the marine forms; the Pterosauria, including the Pteranodontia, containing the flying forms; and the Dinosauria, including the Sauropoda—the giants among reptiles; likewise the Dicynodontia and probably the Theriodontia, among the terrestrial forms. Although but few fossil birds have been found below the tertiary, we have already among the mesozoic forms three new orders: the Saururæ, represented by *Archæopteryx;* the Odontotormæ, with *Ichthyornis* as the type; and the Odontolcæ, based upon *Hesperornis;* all of these orders being included in the sub-class Odontornithes, or toothed birds. Among Mammals, the new groups regarded as orders are the Toxodontia, and the Dinocerata, among the Ungulates; and the Tillodontia, including strange eocene mammals whose exact affinities are yet to be determined.

Among the important results in vertebrate palæontology are the genealogies, made out with considerable probability, for various existing animals. Many of the larger mammals have been traced back through allied forms in a closely-connected series to early tertiary times. In several cases the series are so complete that there can be little doubt that the line of descent has been established. The evolution of the horse, for example, is to-day demonstrated by the specimens now known. The demonstration in one case stands for all. The evidence in favour of the genealogy of the horse now rests on the same foundation as the proof that any fossil bone once formed part of the skeleton of a living animal. A special creation of a single bone is as probable as the special creation of a single species. The method of the palæontologist in the investigation of the one is the method for the other. The only choice lies between natural derivation and supernatural creation.

For such reasons it is now regarded among the active workers in science as a waste of time to discuss the truth of evolution. The battle on this point has been fought and won.

The geographical distribution of animals and plants, as well as their migrations, have received much new light from palæontology. The fossils found in some natural divisions of the earth are related so closely to the forms now living there that a genetic connection between them can hardly be doubted. The extinct marsupials of Australia and the edentates of South America, are well-known examples. The pliocene hippopotami of Asia and the South of Europe point directly to migrations from Africa. Other similar examples are numerous. The fossil plants of the Arctic region prove the existence of a climate there far milder than at present, and recent researches at least render more probable the suggestion, made long ago by Buffon, in his "Epochs of Nature," that life began in the Polar regions, and by successive migrations from them the continents were peopled.

The great services which comparative anatomy rendered to palæontology at the hands of Cuvier, Agassiz, Owen, and others, have been amply repaid. The solution of some of the most difficult problems in anatomy has received scarcely less aid from the extinct forms discovered than from embryology, and the two lines of research supplement each other. Our present knowledge of the vertebrate skull, the limb-arches, and the limbs, has been much enlarged by researches in palæontology. On the other hand, the recent labours of Gegenbaur, Huxley, Parker, Balfour, and Thacher, will make clear many obscure points in ancient life.

One of the important results of recent palæontological research is the law of brain-growth, found to exist among extinct mammals, and to some extent in other vertebrates. According to this law, as I have briefly stated it elsewhere, "all tertiary mammals had small brains. There was, also, a gradual increase in the size of the brain during this period. This increase was confined mainly to the cerebral hemispheres, or higher portions of the brain. In some groups the convolutions of the brain have gradually become more complicated. In some the cerebellum and the olfactory lobes have even diminished in size." More recent researches render it probable that the same general law of brain-growth holds good for birds and reptiles from the mesozoic to the present time. The cretaceous birds, that have been investigated with reference to this point, had brains only about one-third as large in proportion as those nearest allied among living species. The dinosaurs from our Western Jurassic follow the same law, and had brain cavities vastly smaller than any existing reptiles. Many other facts point in the same direction, and indicate that the general law will hold good for all extinct vertebrates.

Palæontology has rendered great service to the more recent science of archæology. At the beginning of the present period a re-examination of the evidence in regard to the antiquity of the human race was going on, and important results were soon attained. Evidence in favour of the presence of man on the earth at a period far earlier than the accepted chronology of six thousand years would imply, had been gradually accumulating, but had been rejected from time to time by the highest authorities. In 1823 Cuvier, Brongniart, and Buckland, and later, Lyell, refused to admit that human relics, and the bones of extinct animals found with them, were of the same geological age, although experienced geologists, such as Boué and others, had been convinced by collecting them. Christol, Serres, and Tournal, in France, and Schmerling in Belgium, had found human remains in caves, associated closely with those of various extinct mammals, and other similar facts were on record.

Boucher de Perthes, in 1841, began to collect stone implements in the gravels of the valley of the Somme, and in 1847 published the first volume of his "Antiquités celtiques." In this work he described the specimens he had found and asserted their great antiquity. The facts as presented, however, were not generally accepted. Twelve years later Falconer, Evans, and Prestwich examined the same localities with care, became convinced, and the results were published in 1859 and 1860.

About the same time Gandry, Hébert, and Desnoyers also explored the same valley, and announced that the stone implements there were as ancient as the mammoth and rhinoceros found with them. Explorations in the Swiss lakes and in the Danish shell heaps added new testimony bearing in the same direction. In 1863 appeared Lyell's work on the "Geological Evidences of the Antiquity of Man," in which facts were brought together from various parts of the world, proving beyond question the great age of the human race.

The additional proof since brought to light has been extensive, and is still rapidly increasing. The quaternary age of man is now generally accepted. Attempts have recently been made to approximate in years the time of man's first appearance on the earth. One high authority has estimated the antiquity of man merely to the last glacial epoch of Europe as 250,000 years, and those best qualified to judge would, I think, regard this as a fair estimate.

Important evidence has likewise been adduced of man's existence in the tertiary, both in Europe and America. The evidence to-day is in favour of the presence of man in the pliocene of this country. The proof offered on this point by Prof. J. D. Whitney, in his recent work,[1] is so strong, and his careful, conscientious method of investigation so well known, that his conclusions seem inevitable. Whether the pliocene strata he has explored so fully on the Pacific coast corresponds strictly with the deposits which bear this name in Europe, may be a question requiring further consideration. At present the known facts indicate that the American beds containing human remains, and works of man, are at least as old as the pliocene of Europe. The existence of man in the tertiary period seems now fairly established.

In looking back over the history of palæontology, much seems to have been accomplished, and yet the work has but just begun. A small fraction only of the earth's surface has been examined, and two large continents are waiting to be explored. The "imperfection of the geological record," so often cited by friends and foes, still remains, although much improved, but the future is full of promise. In filling out this record America, I believe, will do her full share, and thus aid in the solution of the great problems now before us.

I have endeavoured to define clearly the different periods in the history of palæontology. If I may venture, in conclusion, to characterise the present period in all departments of science, its main feature would be a *belief in universal laws*. The reign of Law, first recognised in the physical world, has now been extended to Life as well. In return, Life has given to inanimate nature the key to her profounder mysteries—Evolution, which embraces the universe.

What is to be the main characteristic of the next period? No one now can tell. But if we are permitted to continue in imagination the rapidly converging lines of research pursued today, they seem to meet at the point where organic and inorganic nature become one. That this point will yet be reached I cannot doubt.

THE EFFECT OF SUNLIGHT UPON HYDROGEN PEROXIDE[2]

WE believe that it has not been previously observed that hydrogen peroxide in solution is decomposed by sunlight; it may therefore be of interest to state that during the continuation of our investigations on the chemical effects of sunlight, we found that (1) after about ten months insolation aqueous solutions, containing about 8 per cent. of hydrogen peroxide, were entirely destroyed, and that (2) corresponding solutions shielded from light proved much more stable than is commonly supposed. We are inclined to think that the insolation needs to be prolonged—although we have made no direct observations on this point—because some of the solution, exposed in a thick glass bottle standing in a window, was found to be still of considerable strength after a period sufficient to destroy a corresponding sample in a thin test-tube.

We have elsewhere[3] shown that oxalic acid is destroyed by sunlight by the oxidation of its hydrogen by *external* oxygen, thus:—

$$C_2O_4H_2 + O - = 2CO_2 + H_2O.$$

[1] "Auriferous Gravels of the Sierra Nevada of California." 1879.
[2] By Arthur Downes, M.D., and T. P. Blunt, M.A.
[3] *Proc.* Roy. Soc., vol. xxviii. p. 204.

There is not, we believe, any analogy whatever between that case and this. There we have the "chlorons radicle" C_2O_4 in combination with the basylous H_2, the latter being seized upon by the superior affinity of the external oxygen stimulated under sunlight. Here we may regard the hydrogen peroxide as made up of two atomic groupings of the chlorous radicle HO and, if the theory we suggest be correct, the decomposition in this case is brought about by the dissociation of these radicles. We believe that the tendency of sunlight is to dissociate (or "weaken the internal bonds" between) what we have termed "chlorous radicles," whether these be simple, as oxygen or chlorine, or compound as HO, and thus to promote their combining energy, or to bring about a more stable arrangement of their constituent atoms.

THE FRENCH ASSOCIATION

AMONG the addresses at the Montpellier meeting we must notice that of Col. Laussedat, on geography considered from the point of view of protecting national independence, and on the creation of a French Signal Corps, in imitation of the well-known United States organisation.

M. Broca arrived just in time to give information relating to the Congress of Anthropology which had taken place in Moscow, and at which he had assisted with eleven other French *savants*. The expenses of the journey were paid by the Moscow Anthropological Society and by private donations. The session, the proceedings of which will appear in the *Journal des Missions du Ministère de l'Instruction publique*, and were reported in several French papers, lasted twelve days. M. Quatrefages was considered the head of the party, and gave in their name the loyal Russian toasts in the Kremlin. It is the first time that French *savants* have been entertained in this historical edifice, which was burnt to thwart the designs of the great French conqueror.

M. Chauveau, the Director of the Veterinary School of Lyons, was elected the President for the exceptional meeting at Algiers. The Secretary appointed for this occasion was M. Maunoir, the Permanent Secretary of the Geographical Society of Paris. This election shows that geographical questions will take a prominent place in April, 1881, at the capital of the French colony in North Africa. Much will be heard of the Transaharian, and it is expected that work will be begun on a large scale in the desert on this occasion. The nomination of M. Chauveau took place against the wish of the Council of the Society, who had presented as their candidate M. Baillon, the anthor of the Botanical Dictionary. The appointment of M. Chauvean is considered as a protest against the Haeckelian tendencies of the committee and a revival of the old Montpellier vitalist opinions. At all events, it has created some sensation.

The meeting for 1880 will take place in Rheims, as usual in the month of August, and is sure to be attended by a number of foreign visitors. Great preparations are being made by the local committee to give to the guests an unprecedented reception and to impress upon them a great idea of the peculiarities of the city.

SPECTROSCOPICAL OBSERVATIONS OF SHOOTING STARS

PROF. VON KONKOLY, of the Astro-physical Observatory of O-Gyalla (Hungary), contributes an interesting paper on the spectra of shooting stars to a recent number of the *Astronomische Nachrichten*, from which we note the following data:—On July 26 and 28, and again on August 12 and 13, the Professor had the opportunity of observing some bright shooting stars spectroscopically, and, with a few exceptions, he arrived at the result that the heads of shooting stars give a continuous spectrum generally, upon which very often the bright sodium line appears projected. Since this, however, is not always the case, Prof. von Konkoly inclines to the belief that considerable differences of elevation exist amongst shooting stars, and that those which do not show the sodium line are travelling in very much higher regions than those which do show the line in question, since he looks upon the sodium line as not belonging to the shooting star itself, but as resulting from the atmospheric air which the meteorite condenses and renders incandescent. It is evident that in very high regions there must be very much less (if any) chloride of sodium suspended in the atmosphere than in lower strata.

In the spectra of some of the July meteors a red line was also observed, but a blue one was looked for in vain; yet the professor would not deny that the red line in question may have been a potassium line and that the blue Kβ was simply overlooked on account of its extreme weakness.

The meteors observed on August 12 and 13 resembled those observed in July in almost all details. Thus a yellow meteor of the first magnitude was observed, which evidently originated from the Perseus radiating point. In the spectrum of the head of this meteor, besides the bright sodium line, the lithium lines were distinctly visible; three seconds later another meteor of about the second magnitude passed through the field of the spectroscope in a direction exactly parallel to the former one, and the spectrum of both head and tail in this case was simply a tolerably bright continuous one, without any appearance even of the bright sodium line.

At 10h. 46m. 10s. Prof. von Konkoly saw a magnificent meteor in the north-eastern sky; it moved very slowly, its colour was emerald green, its brilliancy equal to that of Jupiter; he at once directed his spectroscope towards it. At the first appearance the head showed the sodium line only, but soon a number of lines were seen in the green and blue, of which one was recognised as a magnesium line, while others were suspected to be copper lines. There were also two faint lines visible in the red. On August 14 several other meteors were observed with the spectroscope, but only one was seen in the spectrum of which a faint red line appeared besides the sodium line; of these meteors several were of the first magnitude and did *not* show the sodium line; other ones of a lesser magnitude showed the sodium line very brightly besides a continuous spectrum more or less brilliant.

At the same observatory two stationary meteors were observed: one by Capt. von Reviczky on July 26, at 11h. 48m. O-Gyalla mean time (position: 2h. 0m. R.A and 29° 0′ decl. N., magnitude 3); the other by Herr J. Rosenzweig, the assistant at the observatory, on August 11 at 9h. 47m. 1s. O-Gyalla mean time (position: 2h. 14m. R.A. and 55° 18′ decl. N., magnitude 3).

The total numbers of shooting stars of the two showers referred to, which were observed at O-Gyalla were as follows:—

		Meteors.
